IP multicast is an internetwork service that provides efficient delivery of data from one or more sources to a set of recipients, commonly known as a group (Deering 1989). Live video/audio streaming (for example, videoconferencing and collaborative groupware, webcasting), distribution of large amounts of data (for example, software updates to a community of users and applications with shared data, such as whiteboards), periodic data distribution or data feeds (for example, newspaper/magazine distribution, and sport or stock quotes), Web server updates, pay-per-view services (for example, video on demand), and distributed videogames are examples of services that could take great advantage of multicast communication.

Multicast communication can be one-to-many, as in video streaming or webcasting, or many-to-many, as in multiparty computer games or conference calls. In both cases, its goal is to reduce sender transmission overhead, network bandwidth usage, and the latency observed by receivers. If the source can send only one IP multicast datagram, or packet as we interchangeably call it, containing, for example, video information, to multiple teleconference sites instead of one packet per site, network bandwidth is saved and time synchronization is closer to optimal. For this to be possible, special addresses are necessary, so that the source does not have to know who and how many the receivers are, nor it has to specify their address in the packet. Ad hoc routing schemes must also be devised in order to optimize the distribution of the minimum number of packets necessary to reach only all the intended recipients. Furthermore, group management protocols that define how a host may join or leave a multicast group, how a group is started and terminated, how a group address is selected, are also necessary. Because groups are likely to become larger and highly dynamic as multicast usage becomes widespread, membership changes will occur frequently. Therefore, the design of efficient and scalable group management protocols is crucial for the deployment of multicast services in real scenarios.

The first experiments with multicast date back to the early 1990s, when multicast traffic was encapsulated in

traditional unicast datagrams thus defining a virtual network called Mbone (Almeroth and Ammar 1997). Multicast communication is now available by default in the TCP/IP stack. Routing protocols such as OSPF and IGRP use multicast addressing to distribute control messages. Yet, more than fifteen years later, only a limited number of autonomous systems support multicast at the time this chapter is written (see Multicast Technologies 2006), namely 2 percent of the autonomous systems as ranked by Caida (Caida 2006). Research and standardization efforts are still ongoing, however, because some areas have not reached a final development stage or still can be improved (e.g., IETF n.d.a; n.d.b; n.d.c; n.d.d).

Because of the limited deployment of multicast services at the IP layer, overlay multicast, that is, multicast at the application layer, has been proposed as an alternate approach (e.g., Quinn and Almeroth 2001; Birrer and Bustamante 2005; Chu, Rao, and Zhang 2000). Nodes of an overlay multicast group use the underlying unicast IP connections between them and implement all the multicast functionalities at the nodes rather than the routers. Although overlay multicast is easy to deploy and does not need any change in the existing architecture, it may introduce long latencies and packet duplication.

Another criticism moved to the original IP multicast model is its inefficiency when dealing with large numbers of groups with few members each. In this case, the overhead incurred by the network to deliver data to each group outweighs the advantage of a multicast distribution at IP level. A variety of proposals to overcome this problem have appeared in the literature. As an example, we recall here the Small Group Multicast (SGM; Boivie, Feldman, and Metz 2000), where the source knows the group members' addresses and explicitly lists them in the datagram, which is sent as a regular IP unicast packet. No multicast routing protocols are necessary, or group addressing or group management. Although the performance advantage over the IP multicast model is evident when the number of recipients is little, the SGM model radically departs from the IP multicast philosophy. Therefore, as in the case of overlay multicast, we will not investigate it any further.

In this chapter, we review the basic concepts of IP multicast for IPv4 with particular attention to addressing, group management, and routing protocols, as they embody the core of IP multicast. The aspect of reliability and the modifications introduced by IPv6 are also considered.

This chapter is organized as follows: the second section reviews the IP multicast architecture originally proposed by Deering, the third section illustrates multicast addressing, the fourth section focuses on group management, the fifth section describes multicast routing, the sixth section addresses the issues of reliable multicast, and the seventh section gives an overview of IPv6 multicast. Finally, the eighth section summarizes our contributions and concludes the chapter.

THE ORIGINAL MULTICAST MODEL

In this section, we illustrate the basic concepts of IP multicast within the IPv4 context as proposed in the original service model (Deering 1989). IP multicasting is the ability to send IP datagrams to multiple nodes in a logical group, in such a way as to minimize the number of packets. Datagrams are delivered according to the best-effort style of unicast IP. The group is identified by a special IP address, on the range from 224.0.0.0 to 239.255.255.255. Such addresses are statically assigned if the group is permanent, that is, it exists with any number of members, zero included, or dynamically assigned if the group is transient, in which case the group exists as long as there are members. Addresses of permanent groups are published in the “Assigned Numbers” (Reynolds and Postel 1994; Reynolds 2002).

Traffic forwarding is performed by multicast-enabled routers, which will forward the IP multicast datagram outside the local network if it has a time-to-live greater than 1 so that other routers may complete the packet distribution to other group members. No provisions are made for reliable delivery of the packets or for secure services such as encrypted data or closed groups. Figure 1 illustrates the transmission of a single multicast packet to a group of receivers by a source node S. Only multicast-enabled routers (MR) handle the multicast packet.

Group membership is dynamic: hosts may join and leave a group at any time, with no limitations on their number and location. Groups are open and public. Any host can

Figure 1: A typical scenario of multicast service: source S sends a multicast packet to the group members G. Multicast-enabled routers (MR) handle traffic forwarding to the receivers

send to a group, although only group members may receive. As we will see, such a general service model makes the design of efficient protocols for routing traffic, managing groups, and assigning addresses quite challenging.

In what follows, we review the addressing scheme and multicast routing protocols. We then describe how group management is performed and discuss the issues of reliable multicast communication.

ADDRESSING

A multicast group is identified by a particular address, G, which allows a source, S, to send a message simultaneously to all the hosts in the group. This way the source does not need to know the recipient identities and their individual IP addresses do not have to be listed in the IP datagram. Only the group address is necessary to transmit an IP multicast datagram. The notation (*,G) indicates all possible sources for group G, and (S,G) indicates the specific source S for group G. While specific sources are regular IP addresses, G's are multicast addresses only.

Address Allocation

By restricting multicast addresses to a specific range, routers can distinguish them from unicast addresses and handle them accordingly. For this purpose, the Internet Assigned Number Authority (IANA) has reserved class D address space, that is, addresses with the four high-order bits equal to 1110, covering the range 224.0.0.0–239.255.255.255 (Reynolds and Postel 1994). The remaining 28 bits of the address identify the group, for a total of about 268 million groups. Three main groups of addresses can be identified over the reserved range, namely those that are reserved for well-known groups, those that are reserved for Internet-wide communications (globally scoped), and those reserved for local multicast communications (administratively scoped). In each of these groups, some of the addresses may be assigned statically and some dynamically on a per-session basis and reclaimed when the session is terminated. In what follows, we will look at some of the well-known addresses and remind the reader to IANA (n.d.a), 2006 for a complete up to date list.

Although address 224.0.0.0 is not assigned to any group, the addresses in the range 224.0.0.1–224.0.0.255 are reserved for specific purposes and routers do not forward multicast packets with destination address in such a range. The local network segment and network protocols use these addresses for automatic router discovery and routing information exchange. In particular, 224.0.0.1 and 224.0.0.2 identify the permanent groups of all the IP hosts and all routers on the subnet, respectively. 224.0.0.4, 224.0.0.5, 224.0.0.9, and 224.0.0.10 are the sets of routers involved in specific protocols, namely DVMRP, OSPF, RIP2, and IGRP, respectively. Other well-known groups are 224.0.0.12 for DHCP and 224.0.0.22 for the IGMP protocol that reports on group membership.

The range of globally scoped addresses 224.0.1.0–238.255.255.255 is used to multicast data between organizations and across the Internet. Some of the addresses are statically assigned, e.g., 244.0.1.1 for the network time protocol, and the rest are assigned dynamically. The

Table 1: A subset of multicast address blocks assigned by IANA according to RFC 3171

Address range	Type	Usage
224.0.0.0–224.0.0.255	Reserved	Local network control
224.0.1.0–224.0.1.255	Globally scoped	Internetwork control
224.0.2.0–224.0.255.0		Ad-hoc
224.2.0.0–224.2.255.255		SDP/SAP
225.0.0.0–231.255.255.255		Reserved
232.0.0.0–232.255.255.255		Source-specific multicast
233.0.0.0–233.255.255.255		GLOP
234.0.0.0–238.255.255.255		Reserved
239.0.0.0–239.255.255.255	Administratively scoped	Internal distribution

so-called “ad-hoc group” spans the 224.0.2.0–224.0.255.0 range and is assigned to various projects. 224.2.0.0–224.2.255.255 is the range of the session description and session advertisement protocols, which the client uses to determine which group it wants to join. Among the set of dynamically assigned addresses, the range 232.0.0.0–232.255.255.255 is reserved for source-specific multicast (SSM) (Bhattacharya 2003; IETF, n.d.e.), that is, one-to-many groups. This service model has been gaining popularity because it is simpler than the many-to-many or any-source multicast (ASM) of the original proposal and the majority of commercially viable applications, such as video on demand, news casting, and Web updates, are one-to-many. The greater complexity of the ASM model is due to the need for the network to discover all sources for a given group and deliver the traffic to the group members. On the contrary, with SSM, the future group member typically specifies the source when it contacts its router to join a group. In its request, the host specifies both the group and the sender, thus relieving the network from source discovery and simplifying multicast delivery. The statically assigned range 233.0.0.0–233.255.255.255 is known as the GLOP range and is reserved for organizations that already have an autonomous systems (AS) number (Meyer and Lotheberg 2001) and would like to set up a multicast group. Each AS can generate any of the addresses in the 233.X.Y.0–233.X.Y.255 range, where X.Y is the 16 bit sequence corresponding to the AS number, converted in the IP address style.

In order to allow routers to restrict packets distribution within an administrative domain, the address range 239.0.0.0–239.255.255.255 is reserved to internal multicast (Meyer 1998) and is therefore called “administratively scoped.” Packets carrying those addresses are not to be propagated outside the borders of the administrative region. Unlike the globally scoped ones, the administratively scoped addresses do not have to be uniquely assigned, as they are not visible outside their domain. As a consequence, there is a saving in the address space consumption, because those addresses can be replicated in different regions. Another way to restrict the distribution of multicast packets is to use specific values in the

time-to-live (TTL) field of the IP header. This is an inheritance of Mbone but is now deprecated because of the ambiguity resulting from overloading the TTL with both packet lifetime and scope limitation semantic when reconfiguring a distribution tree. Table 1 summarizes a subset of the current address assignment by IANA according to RFC 3171 (Albanna, Almeroth, Meyer, and Schipper 2001).

Address Translation

Unicast Internet IP addresses are translated into link layer addresses by the ARP protocol (Plummer, 1982), which maps an IP address onto the MAC address of the host. Although MAC addresses are unique to each network card, a problem arises with multicast addresses as a single IP multicast address should be mapped onto multiple MAC addresses and it should be possible to differentiate between multicast groups. The IEEE LAN 802.3 (Ethernet) standard specifications define a direct mapping technique to resolve multicast addresses combined with the use of a specific bit, namely the 0-th of the first octet, to indicate a broadcast/multicast address. In order to allow IP multicast address mapping to Ethernet addresses, the IANA has reserved the block of Ethernet addresses 01:00:5E:00:00:00–01:00:5E:7F:FF:FF, that is, those with the high 24 bits set to 01:00:5E, (IANA n.d.b.). Thus, the low order 23 bits of the 28 bits of an IP multicast address replace the low order 23 bits of a 48 bit Ethernet address. It is evident that the mapping is not one-to-one, because 5 bits are not utilized. In fact, 32 different IP multicast addresses converge to the same Ethernet address. This requires that a host be able to filter out multicast packets for other groups with the same Ethernet address.

The reverse mapping, that is, from an Ethernet address to the IP address, is not really a mapping. When a multicast packet at IP level reaches the data-link layer, it becomes the payload of the Ethernet frame, whose address is built as discussed above. If the packet needs to be routed outside the LAN, the border router strips the Ethernet frame, recovering the original packet. Thus no address transformation is necessary.

Address Management Issues

The address assignment scheme described so far has some problems. No central authority exists that allocates multicast addresses upon request. Addresses are allocated in a distributed uncoordinated fashion, thus leading to possible clashes. The address space is limited and may be exhausted, as multicast becomes more popular, which would require address reuse when sessions terminate. The multicast address allocation architecture proposed by the former malloc working group of the IETF copes with these issues by defining a three-layer hierarchical approach to address allocation (IETF n.d.b.; Thaler, Handley, and Estrin 2000). The MADCAP, multicast address dynamic client allocation protocol, allows a host to dynamically request an address to a multicast address allocation server (MAAS) (Hanna, Patel, and Shah 1999). The server provides an address that is unique within its allocation domain, but not necessarily globally unique. Although such an approach provides for scalability and locality of group members, it does not guarantee address uniqueness across the Internet, due to the lack of a central address distribution authority. A partial solution to the problem is provided by the multicast address-set claim (MASC) protocol that allows a router to claim sets of addresses at interdomain level for the MAASs in their domain (Kumar et al. 1998; Radoslavov et al. 2000), although domains do not have to allocate an address set for hosts in the domain to be able to allocate group addresses. A module for managing multicast address allocation in a protocol-independent manner, as well as for managing specific protocols used in allocating multicast addresses, has also been defined (Thaler 2003). The module provides the ability to configure and monitor the status of multicast address allocation within the local domain, answering questions regarding how full a given scope is and who filled it up, who allocated a given address, and whether requests are being met.

GROUP MANAGEMENT

In the original model, multicast groups are public and open, that is, any node can be a source for any group, regardless of its membership in that group, and any node can join any group (Deering 1989). Group members ignore the other members' identity. Routers are in charge of filtering traffic for a given group and then forwarding it on their LAN. The Internet group management protocol (IGMP) defines how nodes join, leave, and interact with their local multicast router. It is used between a node and its immediately neighboring router. The original version of protocol was defined together with the overall architecture and later refined in two subsequent versions.

IGMPv1 and IGMPv2

According to IGMPv1, two types of message are possible: membership queries and membership reports (Deering 1989). Routers periodically query their attached networks to determine which groups have members on them. Hosts reply with a membership report only if they are interested in any of the advertised groups. A host that wants to join a group sends a membership report without waiting for

the router query message. The router then adds the group to the membership list for the interface that received the report, unless it is already present, and begins forwarding the multicast traffic onto the network segment.

In IGMPv1 there are no explicit leave messages. If a host wants to leave a group, it simply does not reply to the router membership query and lets it time out. Because of time out expiration, leave latencies can be even in the order of minutes. In order to improve on leave latencies, explicit leave were added in IGMPv2 (Fenner 1997). Version 2 and version 1 are not interoperable. In case IGMPv1 messages are present, all routers must be configured to use version 1.

IGMPv3

Although IGMPv2 improves on version 1, the service model they both assume has some drawbacks. Because there is no control on sources nor is their location known, establishing a distribution tree is hard but flooding multicast groups is easy. Furthermore, address uniqueness is not guaranteed, as we saw in the Addressing section.

IGMPv3 (Cain et al. 2002) addresses these issues by allowing hosts to specify the list of sources from which they are willing to receive traffic and the list of sources from which they do not want any traffic. Unwanted traffic can be discarded at the network level, thus saving system resources. Specific (S,G) joins and leaves are also possible. The service model converges toward a source-specific paradigm, making distribution tree establishment, source identification, and address collision avoidance easier.

ROUTING

Routing multicast traffic requires that packets be delivered in a more efficient way than simply broadcasting them to the entire network or individually sending them as unicast messages to each receiver, in order to avoid wasting network bandwidth or overloading the sender. With multicast routing, the source sends only a single datagram and the routers replicate the packet along the branches of a distribution tree. The leaves of such a tree are the routers directly connected to the group members, which then deliver the packet to their local network. Building the distribution tree is not easy because routers do not necessarily know where the sender is or who the receivers are, given that groups are open and sources do not have to be part of the group. How the distribution tree is built and what information routers store and/or compute distinguishes the various routing protocols. They are classified as "dense" or "sparse" depending upon whether they are more efficient with densely populated groups, or sparsely populated ones, respectively. Initially the focus of multicast routing has been on intradomain protocols but later interdomain protocols have started to be developed. In this case the internetwork structure rather than the group density is the critical issue.

Dense Protocols

Dense mode protocols were proposed first. They build the spanning tree rooted at the source that connects all

Figure 2: A simple example of “broadcast and prune” strategy. Dotted lines represent the broadcast message; solid lines represent the prune messages

the group member networks, by using the “broadcast and prune” strategy, which is the core of the reverse-path multicast (RPM; Deering and Cheriton 1983), illustrated in Figure 2. The reverse shortest path tree (RSPT; Dalal and Metcalfe 1978) rooted at the source is built by broadcasting a packet to the entire network (dotted lines in the figure) and then pruning all the interfaces toward subtrees that do not have any group members among their leaves. Routers whose domains contain no group members (e.g., G in Figure 2) send prune messages (solid lines) back to the root, which nodes upstream propagate if all of their downstream interfaces have received one (e.g., D, E, B). So, in Figure 2, at the end of the broadcast and prune phase, A will forward multicast traffic only to F and C.

The first multicast routing protocol proposed is a dense protocol based on the RPM approach, namely the distance vector multicast routing protocol (DVMRP; Waitzman, Partridge, and Deering 1988). It builds and maintains its own unicast routing table, regardless of the unicast routing protocol and corresponding tables. For each (S,G) pair, DVMRP builds a new RSPT rooted at the source and keeps state information for each source at every router in the network, regardless of whether there are group members downstream. Packet transmission is geographically scoped using the TTL, although such use is now deprecated, as we discussed in the Addressing section.

Another dense protocol is the protocol-independent multicast dense mode (PIM-DM; see Adams, Nicholas, and Siadak 2005 for the latest specification). PIM-DM uses the existing IP unicast routing protocol and routing tables to forward the multicast traffic. PIM-DM floods multicast traffic through the network and prunes the unwanted traffic, periodically. It supports only source trees rooted at the traffic source. Thus a new tree must be built for each source S transmitting in a given group G.

Sparse Protocols

When groups have few widely distributed members, the broadcasting and prune strategy to build the distribution tree is too heavy from a performance point of view. A more efficient approach is to have nodes that want to receive traffic from a given group send an explicit join message to

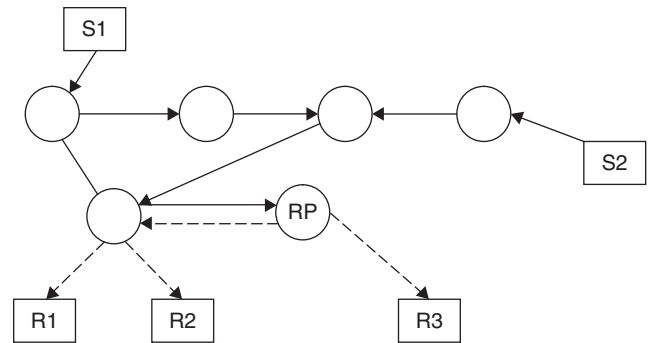

Figure 3: An example of shared tree rooted at the rendezvous point RP. Sources S1 and S2 send their traffic (solid lines) to the RP, which forwards it (dashed lines) to receivers R1, R2, R3

a designated router, known as the rendezvous point (RP) or core, as illustrated in Figure 3. “Sparse mode,” or explicit join, protocols aim at optimizing multicast routing when members are widely distributed. They allow for a better network bandwidth usage, because multicast traffic only flows through links that have been explicitly added to the tree.

Distribution trees are rooted at the RP and are shared by all members of a group, regardless of the number of sources. Sources send packets to the RP, which forwards them to the registered members. Only routers along the distribution tree need to maintain state for each group, thus providing for better scalability with respect to dense mode protocols. However, scalability is limited by the RP, which can be a single point of failure and can easily become a performance bottleneck. Furthermore, it may force the use of less-than-optimal routes between the source and the receivers.

The core based tree (CBT; Ballardie, Francis, and Crowcroft 1993; Ballardie 1997) protocol addresses the drawbacks of DVMRP, in particular the large overhead routers incur when multiple sources and groups are present and the cost of the initial RPM phase when the network is big but few nodes participate in multicast groups. Nodes that are not yet part of the group can send a join request to the core router. The bootstrap router protocol performs RP discovery and selects a backup RP if the primary one fails. Shared distribution trees are updated dynamically as nodes join and leave. CBT uses bidirectional trees to limit the hot spot effect on the RP. Yet, traffic concentration on a single link may result from using a single shared tree for each multicast group, and the core based tree may not be the optimal path between sources and receivers in case of few high data rate sources.

PIM sparse mode (PIM-SM; Estrin et al. 1998) is the explicit join version of PIM-DM designed to overcome the limitations of CBT. Unlike CBT, it allows the system administrator to select different RPs for different groups, thus avoiding the traffic concentration issue and improving on the distribution latency with distribution trees that suits better the group. When a source starts transmitting data, it sends a register message to the RP for its group. The RP sends a join toward the source, which allows the intermediate routers to set up the path between the RP and the source. PIM-SM allows the RP to switch

forwarding from the shared tree to the shortest path tree to a given leaf router depending on traffic conditions. Because of the flexibility in managing distribution trees, PIM-SM scales well to networks of any size. Furthermore, by means of the transport level Multicast Source Discovery protocol (MSDP, Fenner and Meyer 2003), the sources of a group can be known to various RPs. RPs operate as MSDP peers and exchange lists of sources over a TCP connection. They also announce sources within their domains using MSDP. If any of the receivers in a domain are interested in the multicast sources of other domains, data is delivered over the normal delivery mechanism in PIM-SM. When the first-hop router registers the first data packet from a source, before sending it down the shared distribution tree, it encapsulates it in a source-active (SA) message that forwards to all MSDP peers. The SA message contains the address of the source, of the group the source is sending to, and of the RP. Each MSDP peer receives and forwards the SA message to RPs farther away from the originator. SA message routing is performed using the currently available routing tables, whether from BGP or MBGP. When a peer that is an RP receives an SA message, if there is a member of the multicast group in its shared tree, it recovers the data from the SA message and forwards it down the distribution tree. By relying on the distributed nature of the various domains and their RPs, MSDP does not require global source multicast routing tables nor does it require global group membership advertisements by domains with only receivers, thus saving on memory and bandwidth.

Mixed Density Protocol

A different type of protocol is the multicast extensions to OSPF (MOSPF; Moy, 1994), which relies on the link-state routing paradigm of the OSPF unicast routing protocol to deliver multicast packets. MOSPF is considered a dense protocol with respect to control information, but it is a sparse one with respect to data. Each MOSPF router uses IGMP to keep track of group membership status and distribute updates by flooding a group membership link-state advertisement message to the entire domain. This way all routers have the same view of group membership and build the correct tree. On the contrary, data is sent only to receivers that explicitly requested it, thus reducing the protocol overhead.

Interdomain Routing

The routing protocols presented so far are typically employed within a domain, or autonomous system. Core based tree of sparse mode protocols or the amount of resources to maintain status information in routers not on the multicast distribution tree are not acceptable in global deployment. Hierarchical interdomain routing has been proposed to address such issues. The multiprotocol extensions to BGP (MBGP; Bates, Rekhter, Chandra, and Katz 2000) and the border gateway multicast protocol (BGMP; Kumar et al. 1998; IETF n.d.a.; Thaler 2004) are examples of interdomain protocols.

MBGP was the initial response to the need for interdomain routing. It extends BGP-4 with the ability to

provide next-hop information between domains, to provide reachability and policy control for multicast routing, and to route various types of network traffic. BGMP was proposed as the long-term solution to wide-scale interdomain routing, in association with the multicast address-set claim (MASC) protocol for hierarchical address space allocation. It strongly relies on the existence of a domain-oriented address allocation scheme to avoid collisions. BGMP is independent of the intradomain multicast routing protocol. It builds a bidirectional, shared tree of domains using a domain as global root for the distribution tree. Choosing the root domain is a delicate operation in the interdomain case because of administrative issues regarding the ownership of the root domain and the effect on performance that the location of the root may have. BGMP selects the domain of the group initiator as the root domain, hoping that this domain will be the source of most of the traffic.

The complexity of the general nature of the ASM model, that is, any source sending traffic to any group of receivers without any previous notification, the inadequacy of the unicast financial charging scheme, the lack of access control, and its limited scalability are behind the proposal of the source-specific multicast model. As mentioned in the Addressing section, SSM captures the single-source nature of most commercially viable applications, such as file distribution and Internet TV. It simplifies routing significantly because sources are unique and well known, and allows for a new addressing scheme. With the EXPRESS multicast protocol (Holbrook and Cheriton 1999) groups are replaced by "channels," or <source, express destination address> pairs. This solves the problem of address collisions and address space scarcity. Nodes explicitly subscribe to channels, possibly also in an authenticated manner. This allows service providers to guarantee the channel owner exclusive use of the channel and subscribers to receive traffic only from a given channel. A single protocol supports both channel subscription and efficient collection of channel information such as subscriber count. Another proposal in this direction is represented by the simple multicast protocol (SM; Perlman et al. 1999). SM builds on the bidimensional address space proposed by EXPRESS and the shared bidirectional trees of CBT. It identifies groups with <core, multicast address> pairs, which are sent by an end node to the router, thus eliminating the need for core router advertisements. Thanks to its simplicity and scalability, SM is suitable both for intra- and interdomain routing.

RELIABLE MULTICAST

IP multicast is an unreliable service, as it is based on the IP protocol. Because multicast applications typically use UDP as a transport protocol, which is also unreliable, either the applications themselves implement the necessary services to add reliability, or ad hoc reliable multicast protocols are adopted. Military applications are typical users of reliable multicast, for example, "command and control" applications distributed across multiple possibly mobile platforms require a consistent information base to allow the officers in charge to make correct decisions.

To make multicast reliable, the problem of packet corruption and/or packet loss must be eliminated. The total, or partial, packet ordering should also be considered. Error control and possibly congestion control are the techniques adopted to provide reliability. Error control provides a solution to packet loss, whereas congestion control allows the system to maintain a smooth traffic flow.

Error control can be performed reactively, that is, by retransmitting packets when a packet loss is detected, or proactively, that is, by sending redundant data as part of the normal traffic flow. Although the former is more efficient when packets are lost, the latter is better suited for slightly lossy links, that is, links where packets are corrupted rather than lost. Because in this case parity checks and other error correcting codes are adopted, proactive or forward error correction has been considered as an add-on to reliable multicast protocol of the reactive type. Various reliable multicast protocols, such as the scalable reliable multicast (SRM; Floyd, Jacobson, Liu, McCanne, and Zhang 1995), the reliable multicast transport protocol (RMTP; Lin and Paul 1996), the pragmatic general multicast (PGM; Speakman et al. 2001), the light-weight multicast service (LMS; Papadopoulos, Parulkar, and Varghese 1998), or the NACK-Oriented Reliable Multicast protocol (NORM; Adamson, Bormann, Handley, and Macker 2004) have been proposed that follow the retransmission approach.

The way error detection and recovery are performed distinguishes the various protocols. The nature of the applications that requires reliable data transport determines which one is more suitable. When an error is detected, two approaches are possible. In one case, the source receives a negative acknowledgement, or NACK, meaning that at least one node lost a packet. In the other case, the source does not receive all of the expected ACKs confirming the reception of traffic from the receivers. SRM, PGM, LMS, and NORM are NACK-based protocols, whereas RMTP is ACK based. Protocols also differ on how control messages are propagated from a receiver to the source, regardless of their type. This affects the amount of state the source or the multicast routers may have to maintain, hence the protocol scalability, and the amount of bandwidth consumed. Suppression mechanisms are usually in place that eliminate redundant control messages in entire subtrees, to avoid flooding the sender (implosion).

Once errors have been detected, retransmission is required. The issues to be considered in this case are which nodes resend the lost packet and how they resend it. In particular, it can be the source that unicasts the lost packet to the requesting receivers, or nodes in the distribution tree, whether routers or end hosts, that multicast the lost packet to an entire subtree. The goal is to minimize traffic retransmission to nodes that did not request it (exposure). The error detection and recovery strategies affect the recovery latency, that is, the average amount of time it takes to receive a reply after detecting a loss, and the adaptability of the protocol to dynamic membership changes.

Whereas in SRM the source waits for the NACKs and every member may perform retransmission with retransmission suppression in place to minimize traffic

duplication, RMTP channels ACKs through a hierarchy of statically designated "ACK processor" nodes. Such nodes merge ACKs from their subtrees and unicast a single ACK up to their parents. They are also in charge of retransmission, using unicast or multicast depending on the percentage of nodes requesting it. In PGM, each router along the distribution tree forwards only one NACK for every packet loss up to the source, thus reducing the NACK traffic at the source. Routers also selectively retransmit traffic only to the nodes that sent NACKs. In LMS, routers select a receiver in their subtree as their substitute and forward all the control messages to it and redistribute messages from it to the subtree. Thus, the burden that in PGM was on the router in LMS has been shifted to a receiver, thus maintaining the router load light. In NORM, typically adopted in military networks, NACKs are used for transport reliability and congestion control for bandwidth sharing with other transport protocols, for example, Transmission Control Protocol (TCP). Reliable multicast sessions may be set up with limited coordination among senders and receivers. Multicast routing can be reciprocal among senders and receivers or asymmetrical, with unicast return paths. Different types of applications or possibly other transport protocols may use NORM services.

IPV6 MULTICAST

Support for multicast in IPv6 has been made a requirement for the protocol (Hinden and Deering 2006) while it is optional in IPv4. Of the differences with respect to IPv4 multicast, we focus on the new address architecture. A brief overview of the impact of IPv6 on group management and routing is also given.

The IPv6 multicast address space is larger than the IPv4 one and structured using a subset of the bits, which define an address. Multicast addresses are identified by the high order octet with value 11111111, or hexadecimal value FF. The next octet is used for flags (4 bits) and scope definition (4 bits). The remaining 112 bits, of which the network prefix and actual group ID occupy the lower 64 and 32 bits, respectively, distinguish the various groups. Part of the information that in IPv4 is associated with a particular range of addresses is now specified by the combination of flag and scope values. In particular, the transient bit flag distinguishes between dynamically assigned, or transient, addresses, and permanent ones, that is, those statically assigned to well-known groups. Transient addresses are valid only within a given scope, namely node, link, site, organization, or global (Internet wide). On the contrary, permanent addresses are valid regardless of the scope value, that is, a version exists for each scope value. Thus, the same group ID (the low 112 bits) may be used at different locations for transient groups and as a permanent address, simultaneously. Like in IPv4, entire subsets of the address space are reserved by IANA, for example, the all node addresses or the all router addresses. IPv4 well-known groups have their IPv6 equivalent, for example, DVMRP routers are identified by FF02:0:0:0:0:0:4, RIP routers by FF02:0:0:0:0:0:9, and so on. For a complete list of the currently assigned addresses see IANA (n.d.a, n.d.c.).

The translation into Ethernet addresses is also different. Of the 6 bytes of an Ethernet address, the leading two are each set to 33, while the remaining 32 bits are set with the low order 32 bits of the IPv6 multicast address, that is, with the actual group ID. The problem of 1 to 32 mapping between Ethernet and IPv4 addresses does not exist anymore.

In IPv6 the multicast listener discovery protocol (MLD; Vida and Costa, 2004) replaces IGMP for group management. MLD is a subprotocol of ICMP and in its version 2 it is similar IGMPv3. Receivers interested in a particular group must join the group by signaling their local router using MLD, which in turn, routers use to learn whether members of a group are present in their subnets.

IPv6 does not support dense mode routing protocols, PIM-SM being the preferred protocol. Source discovery at interdomain level does not exist, as MSDP is no longer available. Embedded rendezvous points defined at address level are a possible solution for PIM-SM interoperability across various domains. Another alternative is source specific multicast.

CONCLUSION

IP multicast is a fundamental tool for efficient communication of one-to-many and many-to-many services, such as videoconferencing, collaborative work, and periodic data distribution. Its key components are address allocation, routing, and group management. Focusing on many-to-many communication, the original service model makes address allocation and routing complex and heavy for the underlying network. The greater generality of the original model and the intrinsic difficulties that it accounts for have somewhat hindered multicast deployment until recently. To have an idea of how much “experimental” multicast is still considered suffices to compare its diffusion with that of the almost equally as old http, which quickly conquered the world with the World Wide Web.

As a result of the complexity of the original model and the difficulty to force architectural change at network level, various trends have emerged that tend to move away from the original specification along different directions. One direction tends to shift the service paradigm toward easier-to-manage source-specific multicast, as one-to-many communication better suits commercially viable applications, such as video on demand or file distribution. Another direction moves the implementation of multicast services at the application layer, thus pushing the complexity to the edges of the network, according to the Internet philosophy. Along another direction, the popularity of small groups with single senders pushes toward unicast implementations under the sender control, which are more efficient at group level and scale well as the number of such small groups increases. Group management is also being adjusted to fit the less-general service model and allow for closed groups, possibly fee-based, which require restricted data distribution.

Although some of the issues of the IPv4 version have been addressed in the IPv6 version, multicast as an off-the-shelf network component is yet to come for few more years.

GLOSSARY

Addressing scheme: The collection of policies and mechanisms used to restrict access to and usage of system resources to authorized users only.

Group management: The practice of managing multicast group membership.

Multicast: The efficient delivery of information to a group of destinations simultaneously.

Reliability: From a network perspective, the guaranteed delivery of data to the intended recipient(s).

Routing: The means of forwarding logically addressed packets from their local subnetwork toward their final destination.

Scalability: The ability of a system to maintain quality performance or service under an increased system load.

Spanning tree: In graph theory, the tree that includes all the vertices of the graph.

INTRODUCTION

Quality of Service is defined as the capability to provide resource assurance and service differentiation in a network (Wang 2001). As the Internet becomes ubiquitous, network applications with varied requirements emerge. For applications such as checking emails or browsing the Web, reliable data delivery is their key requirement. Applications such as data backup and bulk file transfer need a certain amount of bandwidth. Although for teleconferencing or IP-telephone, they demand timely data delivery to function properly. To support diversified applications, network QoS for resource assurance and service differentiation is essential.

QoS is supported in an ATM network. It provides multiple service classes with deterministic performance. By adopting a circuit-based model, ATM also enables traffic engineering capabilities in ATM networks.

The Internet was originally designed for best effort service. When transmitting packets from their sources to destinations, the routers treat them in an undifferentiated way. Upon arriving at a router, a packet is put into a first-in first-out (FIFO) queue. The queuing delay experienced by the packet depends on the queue length at that time. When traffic is bursty, packets encounter unpredictable network delays and could even be dropped when a queue overflows. Therefore, new service classes are called upon to support QoS on the Internet. To enable such advanced services, routers need to support new forwarding behaviors. Instead of putting all traffic into a FIFO queue, a QoS-capable router should adopt proper classification, queuing and scheduling mechanisms for packet forwarding. In IntServ and DiffServ architectures, new service classes and forwarding behaviors are designed. To set up QoS-capable routers for desired forwarding behaviors and services, resource reservation and resource provisioning are respectively employed.

To satisfy QoS requirements of a large number of customers, service providers need to use their network resources optimally. Conventional IP shortest path routing does not guarantee optimal resource consumption and may sometimes even lead to congestion. Internet traffic engineering is concerned with performance optimization of IP networks. It helps service providers find optimal

routes to transmit traffic across their networks. By enabling explicit non-shortest-path routing, MPLS facilitates the deployment of traffic engineering solutions. When combined together, MPLS and traffic engineering offer service providers powerful tools to better manage their network resources.

This chapter introduces network QoS, its requirements and the basic aspects of major QoS technologies. Much of the material in this chapter is based on related RFCs and existing papers on network QoS including (Kurose and Ross 2002; El-Gendy, Bose, and Shin 2003; Xiao and Ni 1999; Semeria 2000; Semeria 1999; Armitage 2000). Because the subject of network QoS is very complex, this chapter focuses the discussion on wired networks, omitting the QoS issues in wireless or mobile networks.

NETWORK QOS REQUIREMENTS

To obtain QoS, customers must state their service requirements that need to be met by the network. Common parameters used to describe QoS requirements are throughput, delay, jitter, and loss rate (El-Gendy, Bose and Shin 2003). Throughput is the effective rate at which data is transferred. It is measured in terms of how many bits have been transported per second (e.g., bits/sec). This parameter is usually used to specify bandwidth assurance. For example, bit rate guarantees for a flow could be specified in ATM, IntServ, and DiffServ architectures. In addition, bit rate could also be used to express a traffic profile entitled to a service. Delay is the time experienced by a packet while passing through a network, i.e., the time interval between the packet's departure from its source to the packet's arrival at its destination. Usually a maximum bound is used to specify the delay requirement. Jitter refers to the variation in packet delays. There are multiple ways to quantify jitter. For example, jitter can be calculated as the difference between delays of two successive packets in a flow. Packet loss rate is a ratio of the number of lost packets to the total number of transmitted packets. Similar to delay, maximum bounds are specified in QoS requirements for jitter and loss rate.

Besides using absolute values, QoS requirements could also be specified in a relative manner where desired service levels of multiple traffic classes are given according to their

relative importance. DiffServ is purposely designed to support differentiated QoS requirements.

ATM

The development of asynchronous transfer mode (ATM) can be traced back to mid-1980s. It is a multiservice network technology designed for transporting multiple classes of traffic: data, voice, and video. ATM is one of the first frameworks that supports QoS. Its traffic is carried in fixed-size packets (called cells). Each cell has a 5-byte header and a 48-byte payload. The fixed-size cell facilitates high-speed switching. Compared to variable-size packet, the fixed-size cell makes scheduling, queuing and buffer management easier and consequently leads to more predictable behavior. ATM network uses virtual circuits (VCs). Before transmission, a VC needs to be setup between the sender and the receiver. The network layer decides the path for the VC and may also reserve resources along the path for the VC. By careful planning, different levels of services can be provided on these VCs.

ATM provides the following four service models (Kurose and Ross 2002).

- Constant bit rate (CBR) service is used to provide fixed bit rates to connections. The connection is characterized by a peak cell rate (PCR) as the allocated transmission rate. The sender is expected to emit cells at or below this rate. It is ideal for real-time constant-bit-rate audio and video traffic. CBR service provides the applications quantitative guarantees on the end-to-end cell transfer delay (CTD), cell delay variation (CDV), and cell loss rate (CLR).
- Variable bit rate (VBR) service comes in two flavors: real-time VBR and non-real-time VBR. In VBR service, traffic is described using parameters like peak cell rate (PCR), sustainable cell rate (SCR), and maximum burst size (MBS). Traffic transmits at a variable rate that follows these parameters. Real-time VBR service, intended for time-sensitive applications, is ideal for bursty audio and video traffic. It specifies acceptable CTD, CDV and CLR. Same as CBR service, real-time VBR service guarantees quantitative QoS. Non-real-time VBR service is intended for bursty traffic with no tight constraints on delay and jitter. In the service, CTD and CLR are specified. It provides a cell loss rate guarantee.
- Available bit rate (ABR) service is designed for applications that have the ability to adapt their sending rates according to the bandwidth availability. This service is intended for data traffic like file transfer and email. Besides PCR, a user could specify a minimum cell rate (MCR), which is guaranteed to the VC. Depending upon the network congestion, the sender will control its rate between the MCR and the PCR. ABR service provides the application a minimum bandwidth guarantee and allows it to transmit data as fast as possible.
- Unspecified bit rate (UBR) service is a best effort service. No guarantees on rate, delay, jitter and loss are provided. In UBR service, applications could use any leftover bandwidth. Unlike ABR service, no congestion information is fed back to UBR application senders. UBR service is designed for non-interactive data transfer applications.

Despite ATM's sophisticated support for QoS, it is not successfully adopted by end-host applications. The main reason is that the Internet and its TCP/IP protocols have already been widely accepted: the most popular operating systems support TCP/IP and many applications have been developed on the Internet with TCP/IP. However, as a result of the high switching speed and the deterministic performance, ATM has found its way in the Internet backbone, where TCP/IP runs on top of ATM and views an entire ATM network as one link-layer network. Before the emergence of high-speed IP backbone routers and MPLS, IP-over-ATM model has once been a very popular overlay architecture used by ISPs to manage the operation of their networks. In the section on traffic engineering, IP-over-ATM will be discussed in detail.

INTSERV

The Internet was originally designed to provide best-effort data delivery. For having variable queuing delays and packet losses, the Internet could not support real-time applications well. To meet the growing need for real-time service, IETF proposed Integrated Services (IntServ) (Braden, Clark, and Shenker 1994) in 1994. IntServ was designed from the beginning for a multicast environment so that real-time applications such as teleconferencing and virtual reality could be supported.

Service Classes

As an extension to the Internet architecture and protocols, IntServ provides services where end-to-end packet delays could be controlled. Two new services are introduced to the Internet—the guaranteed service (Shenker, Partridge, and Guerin 1997) and the controlled load service (Wroclawski 1997b). The guaranteed service provides firm upper bounds on end-to-end delays. It is a service suitable for intolerant real-time applications that cannot function properly if delay bounds are violated. The controlled load service provides “a quality of service closely approximating the QoS that same flow would receive from an unloaded network element” (Wroclawski 1997b). It is intended for applications sensitive to overloaded conditions, such as adaptive real-time applications. Although delay bounds achieved by the controlled load service are fairly reliable, no quantitative guarantees are provided. Efficiency was the main incentive behind the controlled load service. By relaxing delay requirements, increased network utilization can be sustained.

In both services, to achieve QoS, an application must first reserve sufficient resources in the intermediate routers along its source-to-destination path. Applications should characterize their data flows and specify the desired QoS requirements. Every passing router must support admission control to determine whether a new data flow could be accepted. Adequate resources such as link bandwidth and buffer space are required from each of these routers to meet the flow's end-to-end QoS requirements. Each router should consider the amount of its resources that are already reserved and decide if it can grant the requested QoS to the flow without violating committed QoS guarantees. Once resources are reserved along the path, the application could start transmitting

its data. When a router receives a packet, it classifies the packet and puts it into a corresponding queue. The packet is then scheduled for transmission, using the reserved resources for its flow. Following this procedure, the QoS services are enforced. Figure 1 illustrates the required modules in a router to support IntServ. In the management component of a router, reservation setup and admission control install flow state information for packet forwarding, while classifier, queuing mechanism and scheduler in the forwarding component are those that actually provide the desired forwarding behavior.

Reservation with RSVP

Having presented IntServ services and its enabling components in an IntServ router, next the use of the resource ReSerVation Protocol (RSVP) (Zhang et al. 2001; Wroclawski 1997a) with IntServ services will be illustrated. Same as IntServ model, RSVP was fundamentally designed for a multicast environment. It is receiver-oriented, where a data flow receiver initiates the resource reservation.

enables RSVP to accommodate heterogeneous receivers in a multicast group.

Figure 2 illustrates the use of RSVP resource reservation in IntServ services. The sender first sends a PATH message to receiver(s). In the message, an object, SENDER TSPEC, specifies the traffic that the application expects to generate. ADSPEC is another object included in a PATH message. As the message moves from the sender to the receiver(s), the ADSPEC is updated by intermediate routers to describe properties of the data path, such as the availability of specific QoS control services, and parameters required by those services to operate correctly. For example, C_{tot} and D_{tot} , respectively representing the accumulated rate-dependent and rate-independent queuing delays along a path, are parts of an ADSPEC object for the guaranteed service. Upon receiving a PATH message, the receiver uses the data in the SENDER TSPEC and the ADSPEC to guide its selection of resource reservation parameters. For example, C_{tot} and D_{tot} parameters could be used to calculate a bound on end-to-end packet delay when using the guaranteed

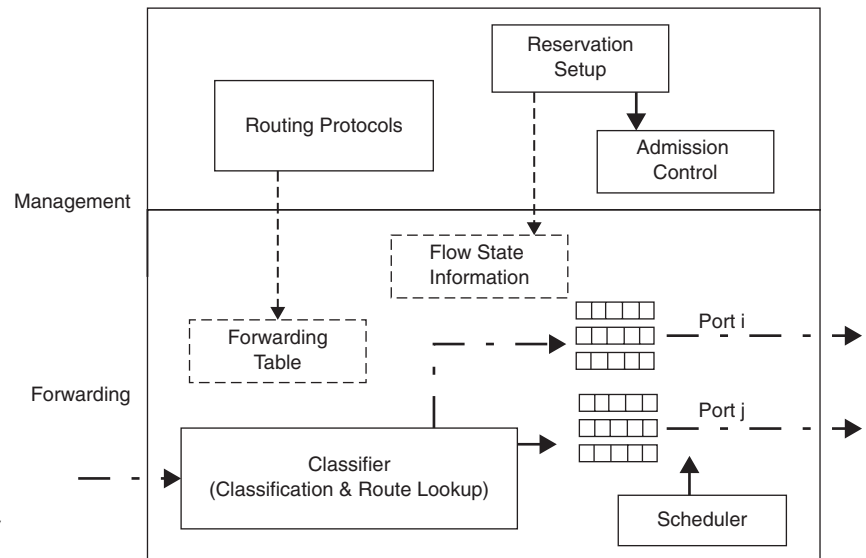

Figure 1: Functional blocks of an IntServ router

Figure 2: RSVP resource reservation

service (Shenker, Partridge, and Guerin 1997). To make resource reservation, a receiver replies back with a RESV message to the sender. In the message, a FLOWSPEC object carries information about the desired flow for the receiver. The desired QoS service (guaranteed or controlled load service) is specified. In addition, tailored to the receiver's individual capability, a receiver TSPEC is included, characterizing the traffic flow the receiver could handle and for which resource reservation is requested. If it requires the guaranteed service, an RSpec parameter is used to describe the specific QoS being requested. For example, RSpec includes a required service rate R for all routers along the path to guarantee the end-to-end delay bound for the flow. Upon arrival of the RESV message, each of the intermediate routers carries out the admission control process locally. If the request is rejected by any of the routers, an error message is sent to the receiver and the resource reservation process is terminated. If the RESV message is accepted by all routers along the path, resources are allocated for the flow and corresponding flow state information is installed in each of the routers so that mechanisms for classifying, queuing, and scheduling the flow's packets are configured properly.

DIFFSERV

As described in the previous section, IntServ provides per-flow end-to-end QoS guarantees. Despite its flexibility in satisfying resource requirements of individual flows, IntServ model is not suitable for the Internet core due to its lack of scalability. IntServ requires each router to keep state information of every passing flow and to support resource reservation, admission control, and sophisticated multifield classification. These cause huge storage and processing overheads on the routers. Besides, only two very specific services, the guaranteed service and the controlled load service, are provided in IntServ framework. No services with different relative importance are supported. To overcome these limitations, IETF developed a more scalable QoS model: differentiated service (DiffServ) architecture (Blake et al. 1998).

To achieve scalability, DiffServ architecture pushes complex management operations to network edges and leaves only simple packet handling and forwarding within the network core. The architecture aggregates traffic into a limited number of service classes. Sophisticated classification, admission control, and traffic conditioning are only required at network boundaries where packets are classified and marked to receive a specific per-hop forwarding behavior in the network. Because resources are

allocated to traffic aggregates and not to individual flows, only per-class state information and simple classification are required in the network core routers. Unlike IntServ, DiffServ architecture not only supports specific services, like the premium service and the assured service (Nichols, Jacobson, and Zhang 1999), but also provides building blocks upon which a wide variety of services can be constructed.

Service Classes

DiffServ can be traced back to RFC 2638 (Nichols, Jacobson, and Zhang 1999), where a two-bit differentiated services architecture is proposed. The document presents two new services: the premium service and the assured service. In the architecture, two bits are used to mark packets, a P-bit for the premium service and an A-bit for the assured service.

For the premium service (Nichols, Jacobson, and Zhang 1999), a small percentage of the total network capacity is allocated to its traffic to create a "virtual leased line." The contracted bandwidth is specified with a desired peak bit rate. The volume of the flow or the aggregated-flow entitled to the service is limited by the peak rate. When the traffic is sent, the availability of the contracted bandwidth will be guaranteed.

For the assured service (Clark and Wroclawski 1997), a traffic profile specifies expected traffic rate and burst size. The assurance is that traffic in the service is unlikely to be dropped as long as it stays within the expected traffic profile.

To provide the premium or the assured services in a network, appropriate packet marking is required at edge routers. Edge routers could use complicated multi-field classification to differentiate incoming packets. The packets will then be marked with a P-bit or an A-bit in their IP headers or left unmarked (e.g., for those best effort packets). Intermediate routers in the network will classify packets and treat them differently simply based on the single bit carried by their IP headers.

Edge routers are configured with traffic profiles for flows or flow aggregations. All arriving packets must be classified based on the content of their headers. If a header matches a configured value, the packet will be passed to the corresponding marker. In the marker, a token bucket has been constructed from the flow traffic profile. For the premium service, the token bucket is very small and can only hold one or two packets. It is filled at the specified peak rate. For the assured service, the token bucket is set by the profile's burst size. It is filled at the expected rate. Figure 3 illustrates how the edge marker works (Nichols, Jacobson, and Zhang 1999). Upon arriving at the premium-configured marker, the packet that sees a token present will be marked with a

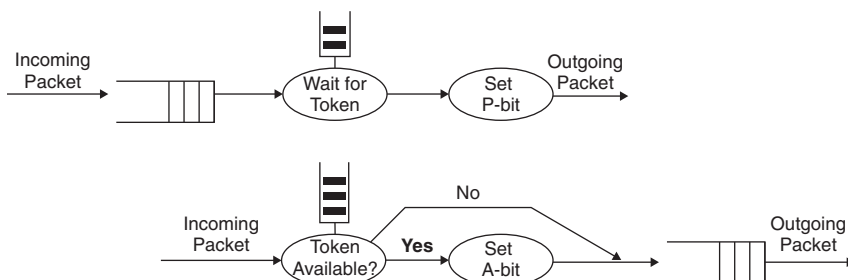

Figure 3: Edge router markers in the two-bit DS architecture

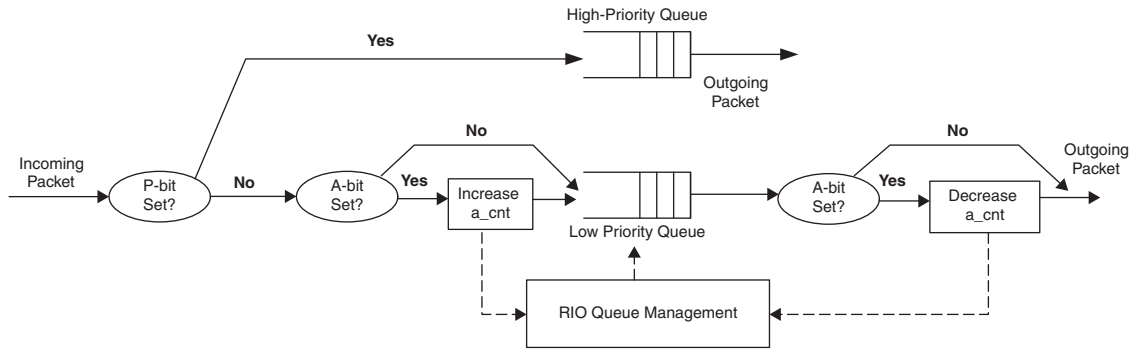

Figure 4: Edge router forwarding in the two-bit DS architecture

P-bit and forwarded. When no token is present, a premium packet is held until a token arrives. For the assured service, the packet will have its A-bit set to one if a token is present. Otherwise, the packet will be forwarded unmarked (i.e., the packet will be treated as best-effort traffic).

To provide different forwarding behaviors to different service classes, the forwarding components (Nichols, Jacobson, and Zhang 1999) of both edge and intermediate routers first put packets into their corresponding queues (Figure 4). If the packet is marked with a P-bit, it enters a high priority queue. Otherwise, the packet enters a low priority queue. The two queues are served by simple priority, with premium packets being forwarded first. As premium traffic flows are shaped, hard-limited to their provisioned peak rates and forwarded first, they will experience little jitter and queuing delay.

The low priority assured queue will be managed using RED in/out (RIO) algorithm (Clark and Wroclawski 1997). It is an extension of the random early detection (RED) scheme. RED manages a queue at a router by dropping packets randomly. This prevents the queue from overflowing, avoids the tail-drop behavior and therefore prevents TCP flows from decreasing and later increasing their rates simultaneously. RIO runs two RED algorithms, one for “in” packets, and one for “out” packets. Two thresholds are used to decide when to start dropping packets in these two RED algorithms. When a lower threshold, based on the total queue length, is exceeded, unmarked “out” packets from the best effort traffic or the out-of-profile traffic will be dropped randomly. The higher threshold, based on the count of the number of A-bit packets enqueued, is used for the “in” RED algorithm to drop assured packets. The “out” RED algorithm drops much more aggressively than the “in” algorithm. This forwarding behavior assures that compliant assured traffic experiences low loss rate even in case of congestion.

Architecture

This section presents the common building blocks of the DiffServ architecture. These building blocks can be used to construct the premium, assured services as well as a wide variety of other services. The discussion in this section focuses on a single DiffServ domain. Interested readers should refer to (Bernet et al. 2000; El-Gendy, Bose, and Shin 2003) for using bandwidth brokers and SLS for end-to-end services across multiple DiffServ domains.

In DiffServ architecture (Blake et al. 1998), traffic entering a DiffServ (DS) domain is classified and possibly conditioned at boundary nodes. Packets are assigned to different classes and will receive different per-hop forwarding behaviors. The class of traffic that experiences the same forwarding behavior at every node within a domain is called a behavior aggregate (BA). Each behavior aggregate is identified by a single DS codepoint in the packet IP header. Nodes will forward a packet according to the per-hop behavior (PHB) associated with its DS codepoint. The DS field in the IP header carries the DS codepoint. It coincides with the (former) IPV4 TOS or the (former) IPV6 traffic class octet (Grossman 2002). The first six bits of the field are used for the DS codepoint (DSCP), and the remaining two bits are currently unused (Figure 5) (Nichols et al. 1998).

- **Traffic Classification and Conditioning.** To receive the differentiated service, a customer must negotiate a service level agreement (SLA) with a service provider. Here a customer could be a user organization or another DS domain. The SLA specifies the service the customer should receive and the amount of traffic entitled to the service. A service provider configures and provisions its routers to meet these SLAs. For instance, a classifier and a traffic conditioner are configured at the edge router to map the customer traffic to appropriate service classes within the provider’s DS domain.

When a packet arrives at a boundary node, the classifier invokes either sophisticated multifield classification or simple BA classification to classify it. The packet is then steered to corresponding traffic conditioner for further processing. Because available resources are finite, only restrictive amount of traffic from a customer is entitled to the requested service level. Therefore, a traffic profile

Figure 5: DS field structure

Figure 6: Logical view of a traffic conditioner

is included in a SLA, specifying the properties of a traffic stream like its rate and burst size. Only in-profile packets are allowed to receive the contracted service level. In the traffic conditioner (Figure 6), which is located in the forwarding component of a DS edge router, the packet is first metered against its traffic profile. The meter determines if the packet is in-profile or out-of-profile. An in-profile packet is marked with appropriate DS codepoint and is allowed to enter the DS domain without further conditioning. An out-of-profile packet may be directed to a shaper where it is queued until it is in-profile, to a dropper to be discarded, or to a marker to be marked with a new DS codepoint indicating an inferior service class. When the packet exits the traffic conditioner of the DS boundary node, DS codepoint of the packet is set to an appropriate value (Blake et al. 1998).

- **Per-Hop Behaviors.** Once being marked, the packet becomes part of a behavior aggregate. It will receive the same per-hop behavior as all other packets marked with the same DS codepoint. A per-hop behavior (PHB) is “a description of the externally observable forwarding behavior of a DS node applied to a particular DS behavior aggregate” (Blake et al. 1998). It is achieved by DS nodes properly allocating resources to behavior aggregates. Complimentary to the traffic classification and conditioning, this basic hop-by-hop resource allocation mechanism is the other key building block of the DiffServ architecture.

A simple example of a PHB is one which guarantees that a behavior aggregate receives a minimal x% of a link bandwidth over some time interval. Another example is PHBs being specified, as a group (PHB group), in terms of relative priority of access to link resources. Two most well-known PHBs finalized by the DiffServ working group are: the expedited forwarding (EF) PHB (Davie et al. 2002) and the assured forwarding (AF) PHB group (Heinanen et al. 1999).

EF PHB (Davie et al. 2002) is intended to provide a building block for low delay, low jitter, and low loss services. The dominant causes of packet delay in a network are fixed propagation delay and queuing delay. EF PHB ensures that EF packets usually encounter short or empty queues, thus experience low queuing delay and low jitter. The packet loss is minimized at the same time if queues are kept short relative to buffer spaces. Short queues are achieved by allocating resources to EF packets with a

higher service rate than their arrival rate. It is guaranteed that EF packets receive service at or above a configured rate. Since this guarantee is made independently of the load of other classes, the low delay, low jitter and low loss EF PHB is protected from non-EF traffic. The DS codepoint allocated for EF PHB is 101110.

AF PHB Group (Heinanen et al. 1999) is used to build services with controlled loss. It divides traffic into four independent AF classes. A DS node must allocate some minimum amount of forwarding resources to each class. Within an AF class, packets are further categorized into three different levels of drop precedence. In case of congestion, packet is discarded based on its drop precedence. As a result, at a DS node, the level of forwarding assurance for a packet depends on the amount of forwarding resources allocated to its AF class, the current load of the class, and when congestion happens within the class, the drop precedence of the packet. Figure 7 summarizes the DS codepoints allocated to AF PHB Group.

MPLS

This section describes multiprotocol label switching (MPLS). In an IP network, when a packet travels from one router to the next, each router makes an independent forwarding decision for the packet. That is, the router analyzes the packet’s header and chooses a next hop for the packet. The process of choosing the next hop could be divided into two steps. In step one, the packet’s header is checked to determine which forwarding equivalence class (FEC) it belongs to. FEC is defined as a group of IP packets that are forwarded over the same path and with the same forwarding behavior. Once the packet has been assigned to a FEC, its forwarding path is determined. Therefore, in the second step, the packet is forwarded to a next hop mapped to its FEC.

In conventional IP forwarding, a router considers two packets to be in the same FEC if their destination addresses map to the same “longest-match” IP address prefix in the forwarding table. This mapping procedure is repeated at every crossing router. The packet is reexamined, mapped to a FEC and then forwarded to a next hop. The forwarding table is constructed and updated using standard IP routing protocols such as open shortest path first (OSPF) protocol, for topology discovery and route determination.

Class	Class1	Class2	Class3	Class4
Drop Precedence				
Low	001010	010010	011010	100010
Medium	001100	010100	011100	100100
High	001110	010110	011110	100110

Figure 7: The recommended AF codepoint values

Figure 8: MPLS header

In MPLS, instead of repetitively mapping a packet to a FEC at each router, a packet only needs to be assigned to a FEC at an ingress router where the packet enters a MPLS network. A packet is then labeled with its FEC as it is forwarded. Subsequent routers do not need to further analyze the packet's network layer header. They forward the packet based on its FEC label.

Each MPLS packet has a header (Figure 8). It is positioned between the link layer (layer 2) and the network (IP) layer headers (Semeria 1999). The 32-bit header contains a 20-bit MPLS label field, a 3-bit class of service (CoS) field that can affect the forwarding behavior applied to the packet, a 1-bit stack field to support a hierarchical MPLS label stack and an 8-bit time-to-live (TTL) field to detect and discard packet looping.

A router that supports MPLS is called a label switching router (LSR). In the forwarding component of a LSR, a label-swapping forwarding algorithm, similar to that used in ATM, is applied. When a packet enters a MPLS domain, an ingress LSR examines the packet and inserts into it a MPLS header. The label carried in the MPLS header is used to identify the packet's FEC. There could be an unlimited number of ways to assign packets to FECs. The considerations could be very complicated but the complexity is isolated from the core LSRs that simply forward labeled packets. After being labeled, the packet is forwarded to the next hop on a label-switched path (LSP). A LSP, similar to a virtual circuit in ATM, defines a sequence of LSRs for a particular FEC. On the LSP, a core LSR uses the packet's input port number and

MPLS label to index the forwarding table. The matched forwarding table entry includes information like the outgoing label, the outgoing interface, and the next-hop address. The LSR then swaps the packet's incoming label with the outgoing label and directs the packet to the outgoing interface for transmission to the next hop on the LSP. Before the labeled packet leaves a MPLS domain, its MPLS header is removed by an egress LSR and it will be forwarded thereafter using conventional IP forwarding.

To construct and update the forwarding table, MPLS applies a standard IP routing protocol and a label distribution protocol (LDP). The standard IP routing protocol is only used to obtain network topology information. After the topology discovery, a LDP is used to construct labeled paths between ingress and egress LSRs. Distinct LSPs are constructed for all FECs of the MPLS network. Figure 9 illustrates the differences between a conventional IP router and a LSR within the network core.

MPLS provides a solution that seamlessly integrates the control of IP routing with the simplicity of layer 2 switching. It provides a foundation that supports the deployment of advanced routing services. Compared to conventional hop-by-hop network layer routing, MPLS has the following benefits (Semeria 1999). First, it gives a service provider tremendous flexibility in the way that it assigns packets to FECs. Second, service providers can construct customized LSPs that support specific application requirements. Third, MPLS can take any type of user traffic, associate it with a FEC, and map the FEC to a LSP that has been specifically designed to satisfy the FEC's requirements.

By deploying MPLS in the network core, an ISP can obtain precise control over the flow of traffic in its network. This unprecedented level of control results in a network that operates more efficiently and provides a more predictable service.

Next, an example is used to illustrate the advantages of MPLS. Figure 10 shows how MPLS supports explicit non-shortest-path routing and thus improves applications' performance. Assume host A is transmitting packets to host C and host B is transmitting packets to host D. If the routers perform conventional OSPF routing protocol,

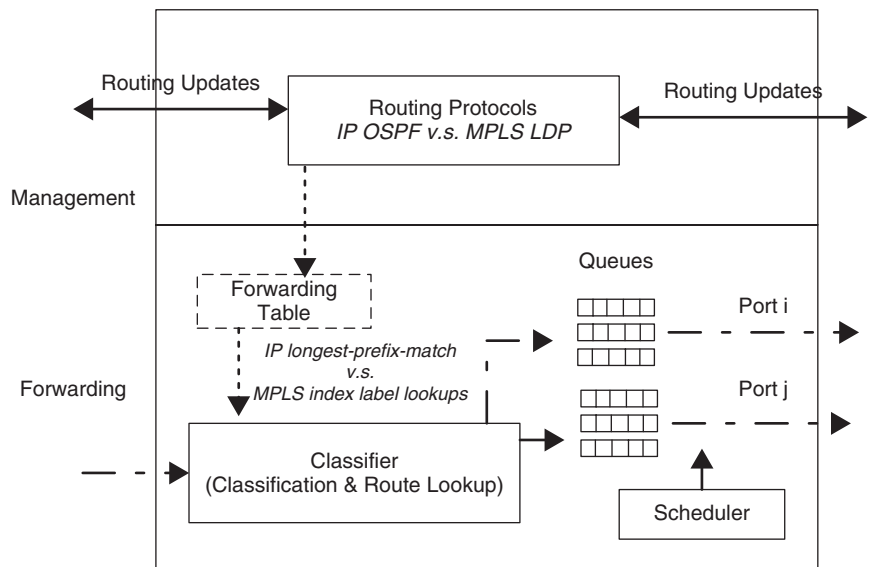

Figure 9: Routing functional components: conventional IP router vs. LSR

Figure 10: Explicit non-shortest-path routing

routes $R2 \rightarrow R6 \rightarrow R8$ and $R1 \rightarrow R6 \rightarrow R8 \rightarrow R7$ will be followed for traffic streams from host A to host C and from host B to host D respectively because they are the shortest paths computed by the OSPF protocol. Suppose congestion is observed at router R8. One policy to reduce the congestion is to reroute some traffic load along different paths across the network. For example, let the traffic originated from host A to host C follow its shortest path, $R2 \rightarrow R6 \rightarrow R8$, and let the traffic from host B to host D follow a new path, $R1 \rightarrow R3 \rightarrow R4 \rightarrow R5 \rightarrow R7$. However, with conventional IP routing, it is difficult if not impossible to support this policy. On the other hand, if the routers support MPLS, it is easy to reduce the congestion at router R8. A LSP1 could be configured to follow route $R2 \rightarrow R6 \rightarrow R8$ and a LSP2 to follow route $R1 \rightarrow R3 \rightarrow R4 \rightarrow R5 \rightarrow R7$. The forwarding tables could be configured so that at router R2, traffic from host A to host C will be associated with a FEC and mapped to LSP1 while traffic from host B to host D will be placed on LSP2 at router R1. The ability to assign any FEC to a customized LSP gives ISPs precise control on how traffic flows through their networks. It provides a foundation that permits them to deliver new services. As another example, MPLS could be used to support service differentiation. An ISP could provision multiple LSPs between each pair of edge LSRs. With careful capacity planning, each LSP could provide different performance and bandwidth guarantees. The ingress router could then place traffic into different LSPs based on the traffic's priority, with high-priority traffic being placed on one LSP and low-priority traffic on another LSP. The three CoS bits carried in the MPLS header also facilitate forwarding service differentiation.

TRAFFIC ENGINEERING

As service providers struggle to keep pace with the ever-growing volume of Internet traffic, one major challenge for them is to provision and manage their network resources to support the committed services and to sustain high rates of growth.

Internet traffic engineering, concerned with performance optimization of operational IP networks, provides important tools for ISPs. The key objective of Internet traffic engineering is to simultaneously optimize network

resource utilization and traffic performance. Its main function is to route and steer traffic through the network in the most effective way so that congestion will be reduced and network resource utilization will be improved.

Process Model

There are four phases in the traffic engineering process model (Awduche et al. 2002). The first phase is the definition of control policies. The control policy is determined by factors like the network cost structure, the operating constraints, and the utility model. The second phase applies a feedback mechanism to acquire measurement data from the network. It enables the network to adaptively optimize its performance in response to changes from inside and outside of the network. The third phase of the process model is traffic characterization and network performance analysis. Traffic characterization investigates the traffic distribution in the network and identifies the traffic workload characteristics. Performance analysis could be categorized into two types. Proactive performance analysis predicts potential problems that may occur in the future, while reactive performance analysis identifies existing problems and diagnoses their causes. Many quantitative and qualitative techniques, such as model-based analysis and simulation, could be applied in this stage. A traffic matrix may be constructed to be used for the network performance optimization. Other results such as identified performance bottlenecks could help guide network design, configuration and capacity planning. The fourth phase is the network performance optimization. It chooses and implements optimization actions. Optimization actions manage either traffic or capacity. Examples include controlling traffic distribution across the network, adding additional links, increasing link capacity, and adjusting routing parameters.

Developments

This section first discusses the limitations of conventional IP technologies for traffic engineering. Then, the popular approach, IP-over-ATM, used by many ISPs to circumvent the limitations is presented. In the end, constrained-based routing and its combination with MPLS for traffic

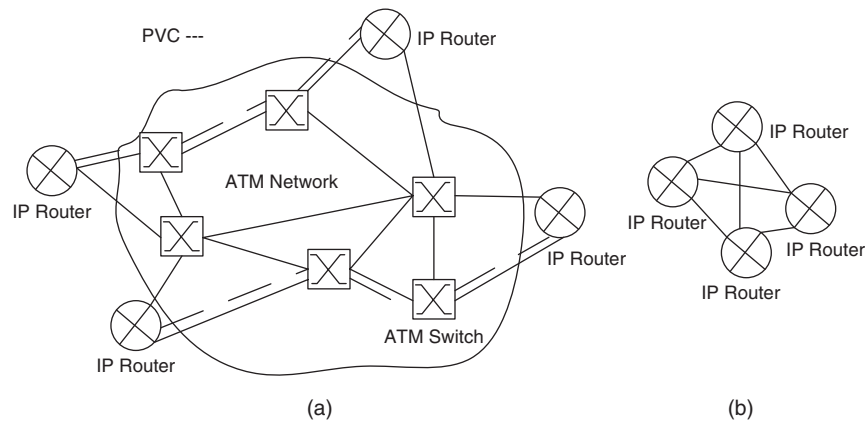

Figure 11: The IP-over-ATM model: (a) physical topology, (b) logical topology

engineering is described. Conventional IP routing is based on shortest path computation using simple additive link metric. When making routing decision, it does not take traffic characteristics and bandwidth constraints into consideration. As a result, conventional IP routing may lead to uneven distribution of traffic, causing congestion as illustrated by the example in the MPLS section. Congestion may also happen when a traffic stream requires more bandwidth than that available on its path. To circumvent these limitations and to have a better control of network performance, IP-over-ATM model has been adopted by many ISPs. It allows ISPs to support the traffic engineering process model in their networks.

Figure 11 shows an IP-over-ATM overlay model. In the ATM backbone, a permanent virtual circuit (PVC) is established between each pair of routers (for the sake of readability, only two PVCs are illustrated in the figure). By using PVCs, ATM cells are transmitted without the need to dynamically set up VCs. Router communicates with each other using PVCs. To the routers, PVCs appear as simple point-to-point links (Figure 11b). IP-over-ATM has been a popular technique adopted by many ISPs to overcome the limitations of conventional IP technologies for traffic engineering. ATM PVCs provide a powerful tool to control traffic across the ATM network precisely. By supporting explicit route of PVCs, traffic could be distributed across the network so that all the links are evenly utilized. This way, congestion caused by conventional shortest path first routing is avoided. In the overlay model, statistics on the PVCs could be used for traffic characterization, which could then be used to optimize PVCs' placement. For example, PVCs' placement could be adjusted dynamically to accommodate shifting traffic loads.

Because of ATM switches' high speed, deterministic performance and traffic engineering capabilities, IP-over-ATM has been widely adopted by ISPs and it permits ISPs to provide better services with lower costs to their customers.

However, there are a few fundamental drawbacks to the IP-over-ATM model. First, it requires the management of two separate networks. Second, it has the n -squared scalability problem. IP-over-ATM requires a full mesh of PVCs, that is, $n \times (n - 1)$ PVCs for n routers. This is only

feasible when the number of routers is relatively small. The difficulties of ATM SAR interfaces to reach very high speed (2.488-Gbps OC-48 speed) and the 20% cell tax only make the scalability problem worse. Third, this solution is not possible over a non-ATM infrastructure.

The emergence of high-speed Internet backbone routers and MPLS makes more integrated and scalable solutions possible for ISPs to successfully manage their networks. As a result, IP-over-ATM model has begun to lose its popularity.

Because MPLS can potentially provide most of the functionality available from IP-over-ATM model in an integrated manner, it plays a significant role for Internet traffic engineering. RFC 2702 (Awduche et al. 1999) listed seven factors that make MPLS attractive for traffic engineering such as lower overhead and supporting explicit LSPs. In the following, one of the MPLS benefits, how it facilitates constrained based routing, is explained.

In traffic engineering, constraint based routing is used to compute routes subject to multiple constraints. To determine a route, constraint based routing considers network topology, flow requirements, link available resources and other policy-related factors. Thus, to do constraint based routing, routers need to distribute new link state information like topology update information and link bandwidth availability information. Such information is then used in constraint based routing to compute routes. When selecting routes, the constraint based routing aims to optimize certain metric such as hop-count, bandwidth, delay, jitter, reliability or cost. For example, the objective for constraint based routing could be to minimize the distance of a k -hop path P defined as $dist(P) = \sum_{i=1}^k \frac{1}{r_i}$, where r_i is the bandwidth

of link i (Xiao and Ni 1999). Once the routes are computed, they will be placed in routers so that the traffic flows will follow them. LSRs could use extended IP routing protocol to exchange link state information. To facilitate route placement, MPLS uses LDP to set up LSPs. MPLS makes constraint based routing at the granularity of traffic trunk possible. Per-LSP statistics in MPLS provide constraint based routing with precise information about the traffic trunk. It helps constraint based routing improve its route optimization.

CONCLUSION AND FUTURE WORK

This chapter introduces major network QoS architectures and technologies. Despite ATM's strong support for QoS, it is not adopted by most network applications. To provide QoS on the Internet, IETF has proposed IntServ, DiffServ, MPLS, and traffic engineering. By properly addressing issues like packet forwarding and routing, these technologies provide service providers powerful tools to efficiently utilize their network resources as well as satisfy their customers' QoS requirements with lower costs.

As introduced in this chapter, there have been many efforts to provide network QoS. However, challenges remain to be addressed before we can easily deploy QoS technologies on the Internet. It is crucial when achieving the required QoS that the networks should still be kept simple, scalable, and manageable. To avoid the complexities associated with most QoS technologies, some service providers such as Sprint (Diot, Meyer, and Whiting 2001) would rather choose over-provisioning of their networks for QoS. Meanwhile, companies such as Cisco are proposing QoS toolset (AutoQoS) (*Service provider* 2003) to simplify QoS deployment. The other challenge that prevents the widely deployment of QoS technologies is their requirement that network elements implement QoS mechanisms. Research (Crowcroft and Oechslin 1998; Singh, Pradhan, and Francis 2004; Subramanian et al. 2004) has recently been conducted on providing network QoS without requiring support from IP routers, where (Singh, Pradhan, and Francis 2004; Subramanian et al. 2004) discuss overlay QoS services. In the future, the integration of network QoS and end-system QoS (see the chapter "End-System QoS") should also be investigated.

GLOSSARY

- BA classification:** The process of classifying packets based on the DS codepoint only.
- Classifier:** An entity which selects packets based on the content of packet headers according to defined rules.
- Flow:** A traffic stream with the same source IP address, source port number, destination IP address, destination port number, and protocol ID.
- Multi-field classification:** The process of classifying packets based on the content of multiple fields such as source address, destination address, DS field, protocol ID, source port number, and destination port number.
- Policing:** The process of discarding out of profile packets by a dropper.
- Queue management:** Controlling the packet queue length by dropping packets when necessary or appropriate.
- Scheduling:** The process of selecting queued packets for transmission.
- Service Provisioning Policy:** A policy which defines how traffic conditioners are configured on DS boundary nodes and how traffic streams are mapped to DS behavior aggregates to achieve a range of services.
- Shaping:** The process of delaying packets within a traffic stream to cause it to conform to some defined traffic profile.

Traffic trunk: An aggregation of flows with the same service class that can be put into a Label-Switched Path (LSP).

INTRODUCTION

When the Internet was created, security was left out of its TCP/IP standards. At the time, the crude state of security knowledge may have made this lack of security necessary, and the low frequency of attacks made this lack of security reasonable.

Today, however, security expertise is more mature. In addition, the broad presence of security threats on the Internet means that security today must be addressed deliberately and aggressively. In 2004, between 5 and 12 percent of all sampled traffic moving across ISP (Internet service provider) networks was malicious (Legard 2004). This chapter describes two ways to add standards-based security to the Internet:

- The first is for users to add standards-based security to individual dialogues, that is, to two-way conversations between pairs of communicating processes. Today, this can be done largely through the use of virtual private networks (VPNs) using the IPsec, SSL/TLS, and PPTP protocols. This “security overlay” approach is not as desirable as good general Internet security standards, but it solves many current user needs.
- The second approach is to add more security to central Internet standards. In addition to the “core three” standards (IP, TCP, and UDP), these central Internet standards include supervisory standards (such as ICMP, DNS, DHCP, SNMP, LDAP, and dynamic routing protocols) and application standards (such as SMTP, HTTP, and FTP). A major effort to retrofit existing Internet standards to add security is underway in the Internet Engineering Task Force under the Danvers Doctrine, but this effort is far from complete.

In this chapter, we will look at these two broad approaches, in the order just presented.

This chapter will not look at security for single network standards, including Ethernet, wireless LANs, asynchronous transfer mode (ATM), frame relay, and the public switched telephone network (PSTN). These individual LANs and WANs operate at the physical and data link layers. As Figure 1 shows, the Internet is a collection of individual LANs and WANs connected by routers. Under normal circumstances, attackers can only send data link layer commands to hosts on their own LAN or WAN. Consequently, for attacks occurring over the Internet, only Internet, transport, and application layer attacks are possible. This chapter focuses on Internet security standards, so it will not discuss attacks on individual LANs and WANs.

This chapter focuses more specifically on TCP/IP internetworking, which is used on the Internet, rather than on IPX/SPX (internetwork packet exchange/sequenced packet exchange), SNA (systems network architecture), and other forms of internetworking, which cannot be used on the Internet. More formally, this chapter focuses on security in TCP/IP standards at the Internet, transport, and application layers.

SECURITY THREATS AND DEFENSES

Before looking at security in Internet standards, we need to consider major security threats and defenses. We will begin with types of attacks because IETF Internet security efforts have focused on one type of attack, namely attacks on dialogues.

Penetration Attacks

One set of threats against which networks must guard is attackers attempting to penetrate into networks and hosts

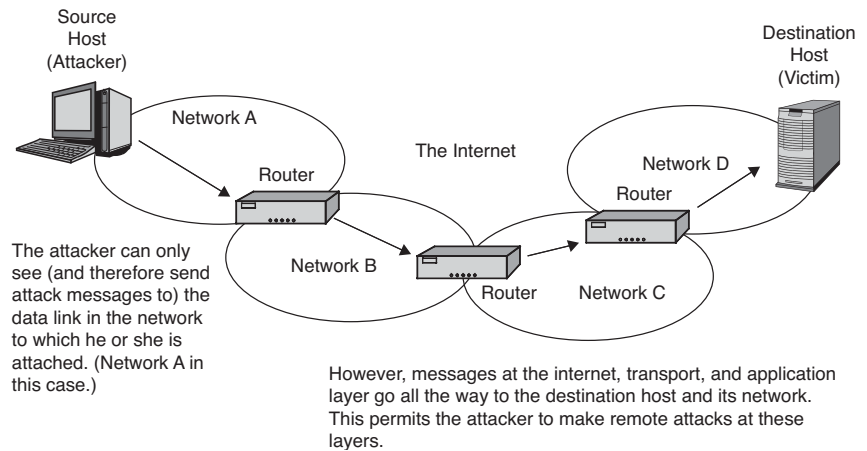

Figure 1: The reason for focusing on Internet layer (and higher) security

by sending probe and break-in messages. These include the following:

- Hacking (when humans intentionally access systems without authorization or in excess of authorization)
- Attempting to conduct denial-of-service (DoS) attacks against networks or hosts by crashing them or overloading them to the point of being useless to their legitimate users
- Automated malware attacks using viruses, worms, spam, and other undesirable content

Attacks on Dialogues

Second, when two parties communicate, they normally engage in a dialogue, in which multiple messages are sent in both directions between two hosts. These dialogues must be secure against attackers who may want to read, delete, alter, add, or replay messages.

An IETF Focus on Dialogue Security

In general, dialogue security has been the main focus of IETF efforts to add security to Internet (TCP/IP) standards. Hacking, DoS attacks, and malware attacks are sometimes addressed, but this is comparatively uncommon. Consequently, we will focus on dialogue security in our discussion.

DIALOGUE SECURITY

In dialogue security, there are three major goals: confidentiality, authentication, and integrity. Confidentiality is relatively easy to provide, and integrity normally appears as a by-product of authentication. Authentication is the most difficult protection to apply, so we will focus the most attention on it.

Confidentiality

Confidentiality means that eavesdroppers who intercept messages en route over the Internet cannot read them. Encryption for confidentiality is the chief tool against unauthorized reading en route.

Encryption is relatively easy to do well if the security developer stays with strong and proven encryption algorithm. In the past, this meant DES and 3DES. Today, this means the advanced encryption standard (AES), which is strong and places a comparatively light processing and memory burden on the communicating devices. AES has also been strongly tested and has survived many attempts to break it. If a security designer does not specify AES, it is incumbent on them to provide a very strong reason for this deviation from good practice.

Authentication and Integrity

Authentication means that the receiver of messages (called the verifier) can verify the identity of the sender (called the applicant or supplicant) in order to ensure that the sender is not an impostor. There are two forms of authentication:

- *Initial authentication:* One side proves its identity to the other side at or near the beginning of a dialogue.
- *Message-by-message authentication:* The sender continues to identify itself with every message, much as parties exchanging letters sign each letter. Message-by-message authentication is crucial to good security.

Integrity means that if a message has been captured and changed en route, then the receiver will be able to detect that a change has occurred. All forms of message-by-message authentication provide message integrity as a by-product. If a message is changed during transmission, either deliberately or through transmission errors, authentication will fail, and the receiver will discard the message.

Initial Authentication

As discussed later, when cryptographic protection systems begin to operate, they usually do initial mutual authentication. Virtual private network (VPN) protocols, which add overlay protection on individual dialogues between hosts, tend to have well-developed initial authentication methods. All three major VPN standards—IPsec, SSL/TLS, and PPTP—have well-defined initial authentication stages.

However, when the IETF adds security to individual existing protocols, such as TCP, it usually implements message-by-message authentication but not initial authentication. Furthermore, it usually does this by providing HMAC (key-hashed message authentication code) authentication, which is discussed later. HMAC requires the two parties to have a shared secret key. Protocols that use HMACs usually are silent on how to distribute these secret keys. Although these keys can be distributed manually, this approach will not scale to large and complex networks.

One possibility for the future is to require protocols to use the extensible authentication protocol (EAP) (Blunk and Vollbrecht 1998), which uses public key authentication with digital certificates for at least one of the two parties. This would work well in many cases in which a server needs to work with multiple clients. Clients can use weaker authentication mechanisms if appropriate.

Kerberos authentication traditionally has used pre-shared master keys between computers and Kerberos authentication servers. Given the weaknesses of this approach, the IETF extended Kerberos to use public keys and digital certificates for initial authentication in 2006 (Zhu and Tung 2006).

Message-by-Message Authentication

Although initial authentication is important, the most complex authentication issues revolve around message-by-message authentication. Consequently, we will focus more specifically on this type of authentication. There are two common message-by-message authentication methods: HMACs and digital signatures. Both are described in more detail in the chapter on electronic and digital signatures. However, we need to discuss them briefly here.

Digital Signatures and Digital Certificates

As discussed in the chapter on electronic and digital signatures, when security uses digital signatures, a bit string called a digital signature is added to each outgoing message. More specifically, the sender creates a message digest by hashing the message and then encrypts this message digest with his or her own private key. Encrypting a message digest with the sender's private key is called signing the message digest. The sender transmits the digital signature along with the original message to the receiver.

As Figure 2 shows, to test the digital signature, the receiver (verifier) must know the public key of the *true party*—the party the sender claims to be. Normally, the receiver obtains the public key of the true party by obtaining the true party's digital certificate. The digital certificate,

among other things, contains the name and public key of the true party. The receiver obtains the true party's digital certificate once and then uses the public key in the digital certificate to test the digital signature in each message.

The receiver must obtain the digital certificate from a trusted certificate authority (CA). One problem with digital certificates is that CAs are not regulated in most countries, leading to questions about their trustworthiness. Although European countries are planning to create regulated CAs, the United States and most other countries are trusting market forces to self-regulate CAs.

It is possible to obtain public keys without using CAs. pretty good privacy (PGP) offers one way to do so. Each user has a “key ring” of trusted public key/name pairs. If User A trusts User B, User A may trust User B's key ring, which may, of course, contain keys received through further distributed trust. If an impostor can dupe even one user, trust in the impostor can spread widely. This is not a good way to manage large public systems of routers, DNS (domain name system) hosts, and other sensitive devices.

Beyond these traditional approaches, efforts are now underway, as noted later in the “Web Services” section, to develop federated authentication methods that allow one-to-one and one-to-few exchanges of digital certificates and other ways to share public keys.

It is also possible to distribute public keys manually. This works well in small systems, but it does not scale well to very large systems.

HMACs

Another tool for message-by-message authentication is the key-hashed message authentication code (HMAC). For HMAC authentication, two parties share a secret key. To send a message, one of the parties appends the key to the message, hashes the combination, and adds this hash (the HMAC) to the outgoing message. To test an arriving message, the receiver also adds the key to the message and hashes the combination. This creates another HMAC. If the received and computed HMACs are the same, the sender knows the secret key, which only the other party should use.

HMACs require less processing power than digital signatures because HMACs only involve hashing, which is a fast process. In contrast, public key encryption and decryption, which are used in digital signatures, are extremely processing intensive.

However, a secret key for HMAC authentication needs to be created and distributed securely for *each pair* of

Figure 2: The need for digital certificates with digital signatures

communicating parties. In large systems of routers and hosts, this can be highly problematic. One approach to reduce this problem is to use public key authentication for initial authentication, and then use the Diffie-Hellman key agreement or public key distribution (using either the RSA or DSA [digital signature algorithm] protocol) to send the secret keys between pairs of communicating parties. However, these approaches only work if there is good initial authentication.

Another “solution” to the key distribution problems is to use community keys, which are shared by all communicating parties in a community. The problem here, of course, is that if a single member of the community is compromised, attackers reading its community key will be able to authenticate themselves to all other members of the community. In addition, community keys are rarely changed because of the need to coordinate the change among many users. When many users are communicating with a key that is rarely if ever changed, a large volume of communication is encrypted with the same key. With a large volume of communication, cryptanalysts often can crack the key. Using community strings for security is a very bad idea.

Another problem with HMACs is repudiation. In repudiation, a party that sent a message denies that they sent it. With digital signatures, repudiation is technically impossible because only the true party should know the true party’s private key, so only the true party could have sent the message. Digital signatures provide nonrepudiation.

However, with HMACs, both sides know the shared secret key. So if the sender argues that the repudiated message was fabricated by the receiver, there is no possible technical counter-argument. HMACs do not provide nonrepudiation.

ADDING OVERLAY SECURITY TO INDIVIDUAL DIALOGUES

As noted previously, the first approach to creating standards-based security is for users to add security to individual existing dialogues. Effectively, this overlays security on the Internet for individual dialogues and works without requiring the creation of completely new Internet standards.

Cryptographic Protection Systems (CPSs)

Secure dialogues require that confidentiality, authentication, and integrity be protected. This is a somewhat complex process involving several phases.

Cryptographic Protection System Phases

Establishing a secure dialogue with a CPS typically involves four sequential phases (although the specific

operations and the order of operations can vary among cryptographic protection systems). Figure 3 illustrates these phases. The first three are quick handshaking phases at the beginning of the dialogue. After the secure dialogue is established, the two parties usually engage in a long ongoing secure conversation.

1. The two parties must select security standard options within the range offered by a particular cryptographic protection system. For instance, in encryption for confidentiality, the system may offer the choice of a half dozen encryption methods. The communicating parties must select one to use in their subsequent exchanges. The chosen methodology may offer several options; these too must be negotiated.
2. The two parties must authenticate themselves to each other. Although initial authentication might seem like it should be the first step instead of the second, the two parties need the first phase to negotiate which authentication method they will use to authenticate themselves.
3. The two parties must exchange one or more secrets (keys are examples of secrets) securely. These secrets will be used in the ongoing dialogue phase that will take place after the initial three “hand-shaking” phases of the CPS are finished.
4. The security of the communication is now established. The two parties now engage in ongoing dialogue with message-by-message confidentiality, authentication, and integrity. Typically, nearly all communication takes place during this ongoing dialogue phase.

The User’s Role

Few users have the training to select security options intelligently, much less handle authentication and other tasks. Consequently, cryptographic protection systems work automatically. The user selects a communication partner, and the systems of the two partners work through the four phases automatically.

At most, users may have to authenticate themselves to their own systems via password, an identification card, biometrics, or some other approach. This user authentication phase tends to be the weak link in CPSs because of poor security practices on the part of users, such as using weak passwords.

The Policy Role

Different security options have different implications for the strength of a cryptographic protection system’s security. Users rarely are capable of selecting intelligently among options. Consequently, companies must be able to set policies for which methods and options will be

Figure 3: Cryptographic protection system (CPS)

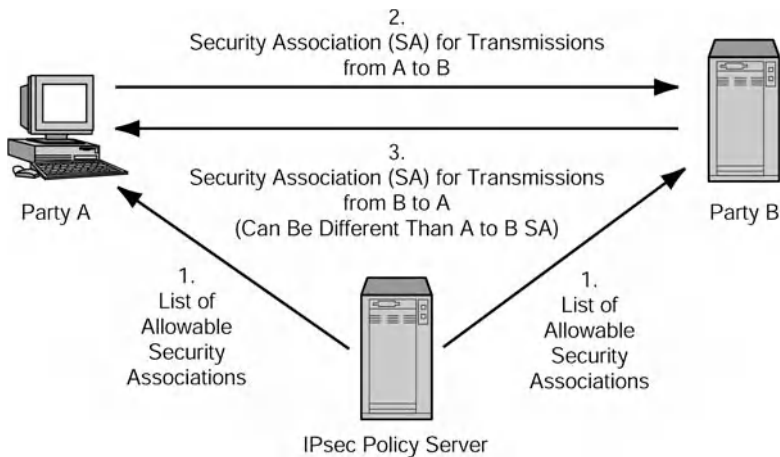

Figure 4: Policy-based security associations in IPsec

acceptable under different circumstances, and they must be able to support these policies by promulgating them and enforcing their use.

Figure 4 shows how policy guides security in IPsec, which we will see later. In IPsec, security often is handled by IPsec gateways. When two IPsec gateways begin to communicate, they establish security associations, which are contracts for how security will be done. A policy server can tell the IPsec gateways what security association parameters they may select or not select. This ensures that the IPsec gateways do not select security associations that are too weak for the traffic they will carry. This approach works with host computers as well as with IPsec gateways.

PPP and PPTP VPNs

Dial-Up Security and PPP at the Data Link Layer

Early computer systems used dial-up security. As Figure 5 shows, the user dialed into a server, generally using the point-to-point protocol (PPP) (Simpson 1994) at the data link layer. Later, companies added security to this approach by creating remote access servers (RASs) for sites. The user dialed into the RAS, authenticated himself or herself (usually with a password), and then received access to all servers at a site or to selected servers.

If a company has several RASs, it normally uses a RADIUS server or some other authentication server to store authentication information remotely, as Figure 5 shows. This way, all RASs use the same authentication

data. Otherwise, if a firm has several RASs, their authentication data may be inconsistent. Adversaries may try different RASs until they find one that is configured incorrectly.

PPP can be used without security, but PPP offers moderately good encryption and several options for authentication ranging from nothing to very strong. Again, the dialogue partners must select the security options they want to employ.

Tunneling

Although PPP is secure, it is limited to a single data link because it operates at the data link layer, as Figure 6 illustrates. However, when a connection is made over the Internet, each connection between a host and a router or between two routers is a separate data link. PPP cannot function over the Internet.

Consequently, Internet-based data link layer security approaches must use tunneling. In tunneling, a data link layer frame is placed within the data field of a packet—the opposite of the usual situation. Placing a message within another message is called tunneling.

The packet is sent from the user computer to the RAS, across multiple links. Finally, the RAS receives and reads the tunneled (encapsulated) frame. Although this effect seems needlessly complex, it allows us to use traditional PPP user-RAS security over the Internet.

Again, when a message is placed inside another message—especially within a packet—this is called

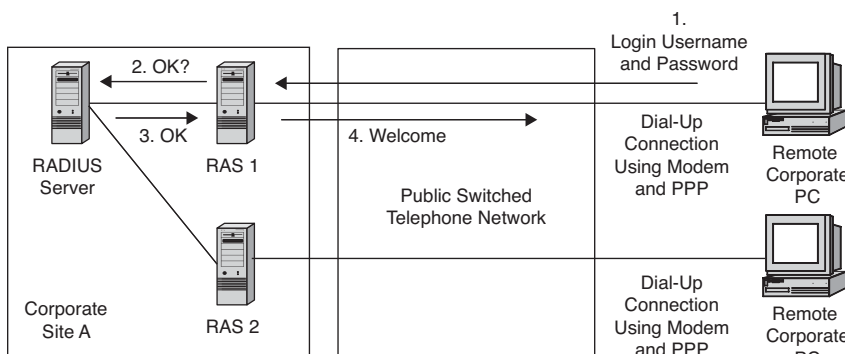

Figure 5: RADIUS authentication

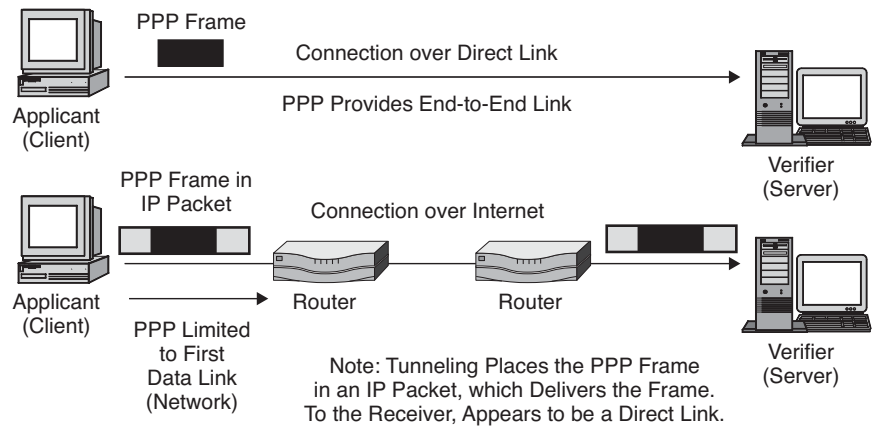

Figure 6: Tunneling PPP

tunneling. We will see later that IPsec also uses tunneling in one of its operating modes (tunneling mode, of course). Tunneling is a delivery technology, not a security technology (Panko 2004). Many security articles and even textbooks confuse the two.

PPTP

The main tunneling protocol for PPP is the point-to-point tunneling protocol (PPTP) (Hamzeh et al. 1999). As its name suggests, PPTP does not have its own security. Rather, PPTP is a way to tunnel PPP frames over the Internet. PPTP uses PPP security methods (encryption and authentication), extending them over an entire Internet connection instead of over a single dial-up data link. PPTP has a number of moderate security weaknesses, but it is good for low-threat or medium-threat environments.

L2TP

Although PPTP works and is attractive, it is limited to transmission over an IP network such as the Internet. The newer layer two tunneling protocol (L2TP) (Tonsley et al. 1999) can tunnel frames over a number of transmission mechanisms, including IP, frame relay, and ATM, to name just three (Tonsley et al. 1999).

However, L2TP does not offer security by itself. It requires users to rely on the IPsec protocol discussed next to provide security at the Internet layer during transit. L2TP is a pure tunneling protocol, not a security protocol at all.

IPsec VPNs

The Internet layer (the OSI network layer) is the core layer in TCP/IP internetworking. The Internet protocol (IP) is the main packet standard at this layer. IP comes in two versions—IP version 4 (IPv4) and IP version 6 (IPv6). IPv4 is the dominant version in use on the Internet today, but IPv6 is beginning to grow, especially in Asia, where relatively few IPv4 addresses were allocated when the Internet was first created.

The IPsec Effort

The Internet Engineering Task Force (IETF) has been working to retrofit IP to be more secure. Their effort has crystallized around a group of standards collectively

called IPsec (IP security) (Thayer, Doraswamy, and Glenn 1998). Although IPsec was initially planned for IPv6, the IETF has developed it to work with IPv4 as well.

Encryption and Authentication

The dominant way to use IPsec is to employ the encapsulated security protocol (ESP) option, which offers both encryption and authentication. We will focus on ESP rather than on the authentication header (AH) option, which only provides authentication. AH is useful primarily when encryption is illegal; this is a rare situation.

Tunnel Mode

As Figure 7 shows, IPsec can operate in two modes: tunnel mode and transport mode. We will discuss tunnel mode first.

In tunnel mode, IPsec is handled by IPsec gateways at the two sites of the communicating parties, not by the computers of the communicating parties themselves. The packet to be delivered securely is tunneled by encapsulating it in another packet, encrypting the original packet, adding authentication, and sending the encapsulating packet from one IPsec gateway to the other. Although attackers can read the IP header of the encapsulating packet, they cannot read the secured packet; nor can they change the secured packet without the change being obvious.

Tunnel mode is attractive because it does not impose expensive installation and configuration burdens on each host. It does not require the individual hosts to have IPsec software on their computers or know how to configure the software. In fact, the users may not even be aware that IPsec is protecting their packets over the Internet. Even more importantly, it is not necessary to obtain a digital certificate for each host and install one on each host if tunnel mode is used; only the IPsec gateways need digital certificates.

The disadvantage of tunnel mode is that it does not provide any protection for the packet as it travels *within* the two sites. The focus is entirely on security during the Internet stage of transmission.

Transport Mode

In contrast, as Figure 7 also shows, IPsec's transport mode offers *end-to-end* encryption and authentication between

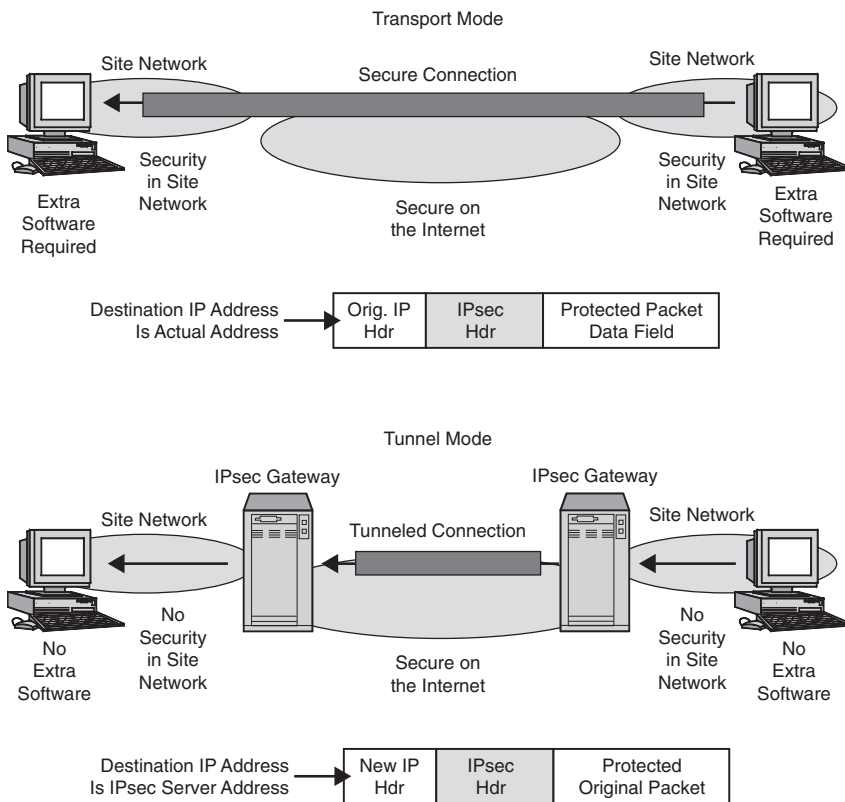

Figure 7: IPsec in tunnel mode and transport mode

the two computers in a dialogue. This approach provides security not only while packets travel through the Internet but also when the packets are passing through local site networks on their way to and from the Internet. Although the Internet exposes traffic to many attackers, there also are dangers within corporate networks. In fact, some of the worst attacks are made by corporate insiders working within corporate networks.

Although the end-to-end security of transport mode is attractive, it comes at a substantial price. Larger firms have thousands or even tens of thousands of PCs. Transport mode requires the configuration of IPsec software and a digital certificate on every PC to be protected. This is extremely expensive.

A more modest problem is that transport mode packets must have the IP address of the receiving computer in the destination address field of the packet header. If sniffers can be placed along the route of these packets, attackers will be able to learn the IP addresses of many corporate hosts. This is a first step in most types of Internet-based attacks. In contrast, tunnel mode packets only have the IP addresses of the receiving IPsec gateway in their destination address fields. This only tells attackers about the IP address of a single machine that usually is well hardened against attacks.

Combining Tunnel Mode and Transfer Mode

One solution to the relative weaknesses of the two modes is to use both. The user can use transport mode to provide end-to-end security but also to use IPsec in tunnel mode between sites to hide IP addresses.

IPsec in IPv4 and IPv6

As noted at the beginning of this section, IPsec can be used with both IPv4 and IPv6. However, with IPv6, the use of IPsec is *mandatory* (Microsoft 2004). With IPv4, however, IPsec is optional.

SSL/TLS VPNs

IPsec is a very complex security mechanism, but it has the advantage of transparency. This means that IPsec protects *all* higher-layer traffic at the transport and application layers automatically, without requiring higher-layer protocols to do any work or even be aware of this protection.

In some applications, dialogues are limited to World Wide Web or at most WWW and e-mail. Under these conditions, the costly burden of implementing IPsec is not justified, and many firms turn to a simpler protocol, transport layer security (TLS), which was originally created by Netscape as secure sockets layer (SSL) and was then renamed transport layer security (TLS) by the Internet Engineering Task Force when the IETF took over the standard's development (Dierks and Allen 1999). If your URL begins with "https," then you are using SSL/TLS.

Whereas IPsec provides a blanket of protection at the Internet layer, SSL/TLS creates a secure connection at the transport layer. This secure connection potentially can protect all application layer traffic. Unfortunately, SSL/TLS requires that applications be *SSL/TLS-compliant* to benefit from this protection. Although all browsers and WWW servers can use SSL/TLS, only some e-mail

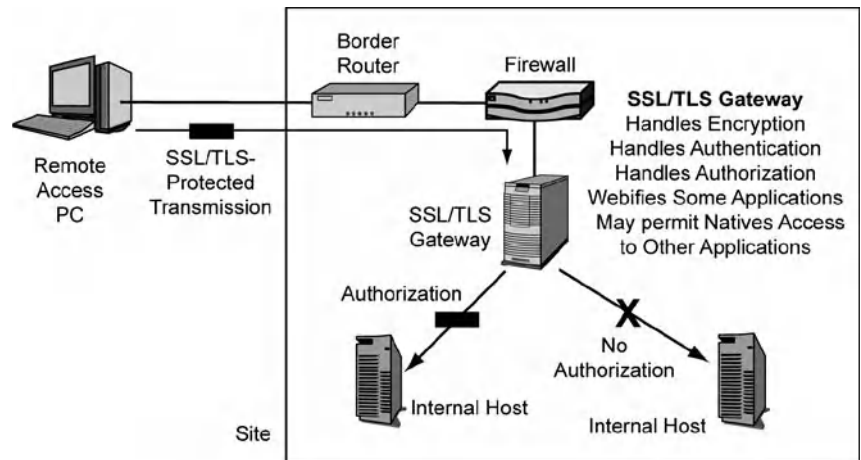

Figure 8: SSL/TLS using gateway operation

systems can use SSL/TLS, and few other applications can benefit from SSL/TLS protection at the transport layer.

SSL/TLS was created for e-commerce, in which a residential client PC communicates with a merchant server. SSL/TLS requires the merchant to authenticate itself to the client using digital certificates and digital signatures. However, few residential client PC owners have digital certificates. So while SSL/TLS permits client authentication using a digital certificate, it makes client authentication optional. This lack of mandatory client authentication is a major security vulnerability that is intolerable in many situations. If SSL is used in dialogue security, client authentication should be required.

Vendors have begun to create semiproprietary techniques to create remote access SSL/TLS VPNs for corporate use, and these techniques have become very popular. As Figure 8 shows, the user firm places an SSL/TLS gateway server at each site, and users have an SSL/VPN connection to this gateway server. The gateway server provides initial client PC authentication using passwords or some other proprietary mechanism. The gateway server then connects the user to internal servers.

SSL/TLS gateway servers can even get around the limitations of SSL/TLS's HTTP focus. Of course, they can protect HTTP traffic easily because SSL/TLS does this automatically.

In addition, most SSL/TLS gateways can "webify" non-HTTP applications such as Microsoft Outlook—sending screen images over HTTP. If the browser will accept a downloaded add-in, many SSL/TLS gateways can even give the user protected access to traditional applications. However, both webification and application access via browser downloads requires proprietary techniques.

The main attraction of SSL/TLS is that the user can use any PC that has a browser, including those in Internet cafes. Unfortunately, trace information from the user's session continues to reside on the PC after the session. Plug-in browser software to remove these traces can be added to the browser, but this requires operating system privileges that users are not likely to have when they work on PCs in Internet cafes.

Multilayer Security

As Figure 9 shows, security can be applied at several standards layers. A major principle of security is defense in depth. Vulnerabilities are discovered in almost all security protections from time to time. Until they are fixed, the attacker has free access—unless the attacker must break through two or more lines of defense. With multiple protections in place, the company will still be protected while it repairs a broken security countermeasure.

Consequently, companies would be better protected if they added dialogue security to more than one layer, say by implementing both IPsec and application security. However, this is expensive, so it is not common.

Dialogue Security and Firewalls

Although adding security to dialogues passing through the Internet is attractive, it creates problems for firewalls. Firewalls need to examine arriving and leaving packets. However, almost all cryptographic protection systems encrypt packets for confidentiality.

Unless these packets are decrypted before passing through the firewall, the firewalls cannot scan their packets for attack signatures. Consequently, companies that

Layer	Cryptographic Protection System
Application	Kerberos
Transport	SSL/TLS
Internet	IPsec
Data Link	PPP, PPTP
Physical	Not applicable. No messages are sent at this layer—only individual bits.

Figure 9: Multilayer Security

buy added security by implementing cryptographic protection systems (CPSs) tend to lose some scanning security. This places a heavier burden on end stations to do scanning, and many end stations are client PCs whose owners lack the willingness, much less the knowledge, to do packet scanning.

One solution is to decrypt all incoming packets before they reach the border firewall, by placing a cryptographic gateway between the border firewall and the border router. However, this leaves the cryptographic gateway unprotected from Internet attacks. If the cryptographic gateway is taken over by attackers, the results can be disastrous.

ADDING SECURITY TO INDIVIDUAL INTERNET STANDARDS

Although adding dialogue security to individual dialogues works, it would be better for Internet standards themselves to offer high security. For instance, if DNS servers are disabled so that clients cannot find application servers, dialogue security will do little good.

When the Internet was first created, none of its standards offered any security. Today, several TCP/IP standards offer security. Unfortunately, the closer you examine their security features, the less adequate many appear. Fortunately, the IETF has a program to add security to a broad range of existing Internet standards individually.

A Broad IETF Commitment

The IETF efforts we have discussed so far are not isolated actions. The IRTF has a broad programmatic commitment to increasing the security of its standards.

The Danvers Doctrine

In 1995, a meeting of the IETF in Danvers, Massachusetts, reached a consensus that the IETF should develop strong security for all of its protocols (Schiller 2002). Originally, the consensus was limited to a decision to use strong encryption keys rather than weak encryption keys that met existing export restrictions. Soon, however, this Danvers Doctrine expanded into a consensus to develop strong security for all TCP/IP protocols. As a first step, all RFCs are now required to include a section on security considerations. As we will now see, considerable progress has also been made in adding security to individual TCP/IP standards.

User Choice

Although all TCP/IP standards are to be given strong security, the IETF decided that it should be the option of individual organizations whether or not to implement security in individual protocols. In part, this decision reflects a desire not to force security on anyone. In part, it also reflects the fact that some networks are in protected environments that do not require security. However, an important consequence of the decision to leave security up to organizations is that organizations must decide which security options to use or not use.

There are five broad layers of functionality in networking—physical, data link, Internet, transport, and applications. Implementing security at all layers would be horrendously expensive and generally unnecessary.

Consequently, many organizations will only want to implement security at one layer. Although this would provide security, individual security technologies often are found to have vulnerabilities. To maintain protection during these periods of vulnerabilities, organizations probably will want to implement security in the protocols at two layers at least, as noted earlier.

Security and Vulnerabilities

Security in Protocols

In discussing the security of Internet protocols, there are two issues. One is whether security has been built into the protocol at all and to what degree it has been placed in the protocol. This is the aspect of Internet protocol security we focus on in this chapter.

Protocol and Implementation Vulnerabilities

Another aspect of Internet protocol security is whether the protocol or its implementation has vulnerabilities that attackers can exploit. In some cases, the protocols themselves are exploitable because of design oversights. In more cases, vendor implementations cause problems. For instance, both the BIND program, which is dominant for Domain Name System servers, and the Sendmail program, which is dominant on UNIX SMTP servers, have had long and troubled histories of security vulnerabilities.

Implementation vulnerabilities are especially dangerous when the same flaw is discovered in multiple vendor code bases. (For example, in February 2001, two major vulnerabilities were found in the simple network management protocol [SNMP] version 1 programs of multiple vendors.) This too can result in Internet-scale disruptions.

The worst-case scenario is a serious vulnerability in a protocol itself because this will affect all products and may take some time to change. In 2003, for example, the TCP Reset vulnerability was discovered. It is difficult to insert messages into a TCP segment stream because TCP uses 32-bit sequence numbers. This gives more than four billion possible sequence numbers. An attacker normally must guess the precise next sequence number that the receiver is expecting. However, TCP acknowledgements contain a Window field. In an odd choice, the TCP standard specifies that if a TCP segment has its RST (reset) bit set, then the receiver will accept *any* sequence number within the Window range. This greatly reduces the number of sequence numbers an attacker must try to cause the target to accept a RST message, which will break its connection with its communication partner. This is a DoS attack. BGP (border gateway protocol), which has long sessions and uses large Window size values, is especially vulnerable to this attack. This is disturbing because BGP is critical for exchanging routing information between Internet core routers and between corporate border routers and Internet core routers. As discussed in the section on BGP later in this chapter, using TCP authentication can reduce the TCP Reset danger.

Lack of Code Diversity

For some protocols, a single code base is used by most or all vendor implementations. For instance, most DNS servers use BIND. In e-mail, use is dominated by Sendmail on UNIX systems and Exchange on Microsoft mail servers. This means that if a vulnerability is found, an attack can produce Internet-scale disruptions. This is called the “potato famine” problem because the Irish potato famine was caused by a lack of genetic diversity in the Irish potato crop. The failure of many systems due to the same problem is also called a common mode failure.

Tardy Patching

In addition, when vendors release patches for vulnerabilities, many firms fail to install patches quickly or at all. This makes some vulnerabilities exploitable for weeks, months, or even years after they are discovered. All too often, firms only patch vulnerabilities in earnest when a virus or hackers create widespread damage.

Perspective

Although protocol and implementation vulnerabilities are important, they are situation-specific. This chapter focuses on security within Internet standards themselves.

The Core Three: IP, TCP, and UDP

There are three core standards at the heart of the Internet: IP, TCP, and UDP.

IP

The main job of the Internet protocol (IP) (Postel, RFC 791, 1981) is to move packets from the source host to the destination host across the Internet, which consists of thousands of networks connected by routers. IP is a hop-by-hop protocol designed to govern how each router handles each IP packet it receives.

A packet may travel over one to two dozen routers as it passes from the source host to the destination host. Many core routers in the Internet backbone handle so much traffic that they can barely keep up with demand. To reduce the work done on each router, IP was designed as a simple, unreliable, and connectionless protocol. Although packet losses on the Internet are modest, IP is a “best effort” protocol that offers no guarantee that packets will arrive at all, much less arrive in order. Given this minimalist vision for IP, it is hardly surprising that security was completely left out of IP’s core design. Given continuing router overload, it would be difficult to make IP secure throughout the Internet.

IPsec was created to add security to IP, making IPsec at least somewhat more than a security overlay method. However, IPsec cannot achieve its promise without a truly worldwide system of certificate authorities.

TCP

To compensate for IP’s unreliability at the Internet layer, TCP/IP was given a reliable sibling protocol, the transmission control protocol (TCP) (Information Sciences Institute 1981) at the transport layer. However, TCP was not created with security. When TCP was created in the early 1980s, security technology was far too immature to

be implemented. Today, there are no plans to add security to TCP given the IETF’s focus on IPsec and IPsec’s capability to provide security for higher-layer protocols. Later, however, we will see that TCP does have an authentication option, but it is only used in BGP.

UDP

When transport layer error correction is not required or is not practical, applications specify the user datagram protocol (UDP) (Postel 1980) at the transport layer. Like TCP, UDP was created without security and is also is not likely to receive security extensions because of the IETF’s reliance on IPsec to protect UDP.

Administrative Standards

The “core three” Internet standards do most of the work of the Internet. However, several other administrative protocols are needed to keep the Internet functioning. We will look at security in the most important of these standards.

ICMP

IP merely delivers packets. It does not define any Internet layer supervisory messages. To compensate for this lack, the IETF created the Internet control message protocol (ICMP) (Postel, RFC 792, 1981) to carry supervisory information at the Internet layer. ICMP messages are carried in the data fields of IP packets. ICMP messages allow hosts to determine if other hosts are active (by “pinging” them). ICMP also allow hosts to send error messages to other hosts and allows hosts to tell other hosts or routers to act differently than they have been acting. ICMP is a powerful tool for network managers.

Unfortunately, this power also makes ICMP a popular tool for hackers. Making ICMP less useful to hackers would also tend to make it less useful to network administrators, so the IETF has done nothing to implement ICMP security. For this reason, most corporate firewalls block all ICMP traffic except for outgoing pings (echo messages) and returning pongs (echo reply messages).

If ICMP were given good authentication, however, corporations might be more willing to allow it through firewalls. In addition, authenticated ICMP would protect against attacks generated within the firewalls at individual sites. However, there are no current IETF activities to add authentication and other security to ICMP. The reason may be that ICMP messages are carried in the data fields of IP packets, which can be protected by IPsec, including the authentication of the sending ICMP process.

Domain Name System (DNS)

Richard Clarke, former National Coordinator for Security, Infrastructure Protection, and Counter-Terrorism for the President of the United States, has characterized the domain name system (DNS) as one of the two greatest danger points on the Internet. (Later we will look at the second item on Clarke’s list, BGP.)

In a sense, DNS is the telephone directory of the Internet. The DNS allows a source host to find the IP addresses of a target host if the source host only knows the target host’s host name (Mockapetris 1987).

The domain name system has multiple servers organized in a hierarchy. These are called DNS servers, or, sometimes, name servers.

There are two likely attacks on DNS servers. First, attackers may be able to “poison” the databases in DNS servers. When user computers send DNS request messages to poisoned servers, they will get incorrect IP addresses that send users to pornography sites, to sites containing Trojan horses, and to other undesirable sites. Companies can even poison their competitor’s DNS listing so that all e-mail messages go first to the attacking company before being relayed to the victim’s mail servers.

DNS poisoning is not just a theoretical concern. As long ago as 1997, users trying to reach InterNIC.com twice found themselves redirected to a competitor, alterNIC.com. The redirection episodes only stopped when a judge ordered alterNIC.com to stop the redirection. At the time, InterNIC.com was the only registrar for .com, .edu, .org, and .net. There have been many other instances of DNS poisoning since then. DNS poisoning is also known as DNS spoofing.

To address problems with DNS poisoning attacks, the IETF DNSSEC (DNS security extensions) Working Group is developing an authentication approach based on public key encryption with digital signatures (Rose 2002). There are a (relatively) limited number of high-level DNS servers, so giving each a public key and a private key is not too daunting a challenge. As long as DNS servers do not get taken over so that their private keys can be stolen, authentication should be very good. Complicating matters somewhat, in mid-2004, the DNSSEC Working Group created *bis* versions of most of its RFCs to make DNSSEC somewhat weaker but easier to implement. Although DNSSEC is incomplete, a number of DNS servers now support its main elements. For more information, go to www.dnssec.net.

In addition to poisoning attacks, there is the possibility that attackers will use DoS attacks to make DNS servers unavailable to users. Most client users only know the host names of the servers they use. Consequently, if the DNS were to fail for some period of time, clients could no longer reach servers.

As noted earlier, DNS is hierarchical, and if all DNS servers at the highest level are subjected to successful DoS attacks, clients would soon begin to lose the ability to access many servers. At the top level of the DNS server hierarchy, there are only thirteen root DNS top-level domain (TLD) servers run by ten different organizations; one of them periodically feeds changes to the others. Nearly all of these servers, furthermore, use the BIND DNS server program, which has a long history of vulnerability.

Although these root DNS hosts are geographically distributed, most use the same software, leaving them open to common mode attacks if vulnerabilities are found. Also, geographical distribution is not strong protection when there are only thirteen targets to attack. In late 2002, a brief DoS attack degraded the service given by nine of the thirteen root DNS hosts. Had this attack been more intense, and had it continued over many hours or even some days, service disruption would have begun across the Internet.

The threat raised by such concentrated DNS resources is very real. The root DNS servers are well protected with both technical and human protections. However, below the root servers are top-level domain (TLD) DNS servers for the various generic (.com, .edu, etc.) and national (.jp, .ca., etc.) TLDs. The degree to which the DNS servers of these TLDs are distributed and have code diversity is unknown.

In addition, there are literally tens of thousands of corporate second-level domain DNS servers. Firms are required to have two and preferably three DNS servers. However, if these two or three servers are attacked, corporate communication will stop.

In traditional DNS, only the host names and IP addresses of servers are recorded. However, DNS has been extended by the IETF to dynamic DNS (DDNS). In this newer protocol, clients that receive temporary IP addresses from DHCP (dynamic host configuration protocol) servers can register their temporary IP addresses with the firm’s DNS server. This is very good because it extends the usefulness of DNS. However, it raises obvious poisoning security concerns that have not been addressed by the IETF.

In addition to protecting DNS, the IETF has moved toward making DNS records a place to store security keying information. (RFC 4025 described how to do this in IPsec, and RFC 4225 did the same for SSH.)

Simple Network Management Protocol (SNMP)

The goal of the simple network management protocol (SNMP) is to allow a central administrative computer (the manager) to manage many individual managed devices. Figure 10 shows that the manager talks to an agent on each device. The manager does this by sending the managed devices Get messages (which ask for information on the device’s status) or Set messages (which tell the managed device’s configuration).

Obviously, SNMP is a powerful management tool. Unfortunately, it also is a golden opportunity for attackers. It potentially allows attackers to learn a great deal of information about target networks through Get commands. It also allows them to inflict an endless amount of damage through the malicious use of the Set command to create misconfigurations on large numbers of devices. These misconfigurations can make the devices unusable or can even make the devices interfere with the operation of other devices.

SNMP version 1 had no security at all, making the protocol extremely dangerous given its power. SNMPv2 was supposed to add security, but an inability to settle differences within the IETF prevented full security from being built into SNMP.

Version 2 did receive one authentication advance. To send SNMP messages to a version 2 SNMP agent, a manager would have to know the agent’s “community string,” which is like a password. In practice, most firms have all of their agents use the same community string. In fact, many do not even change the vendor’s default community string, which often is “public.” In any case, SNMPv2 sends community strings in messages without encryption, so attackers with sniffers can quickly learn community strings.

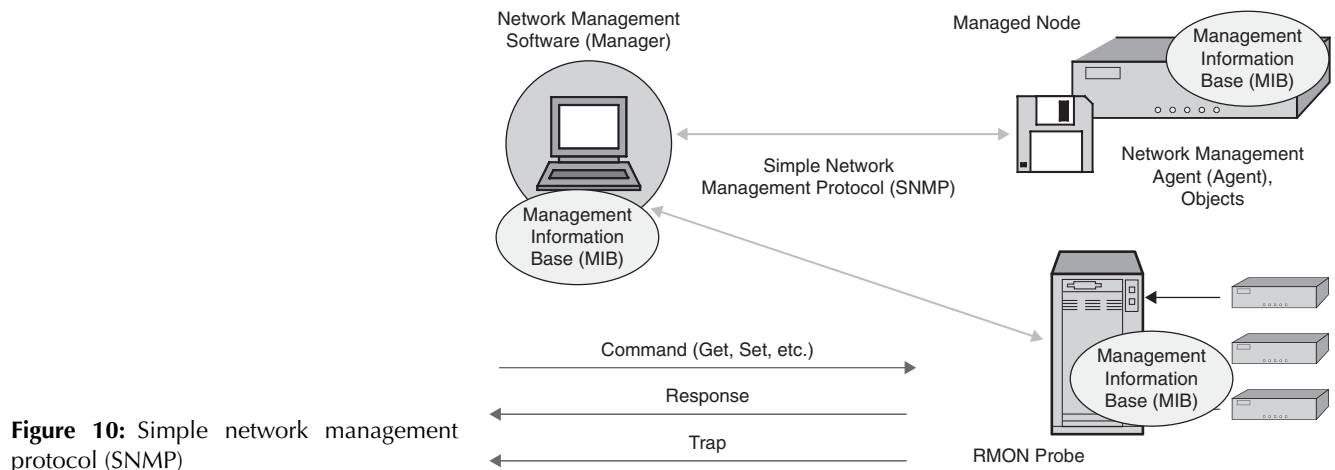

Figure 10: Simple network management protocol (SNMP)

There actually are four different possible community strings for manager-agent communication: read-only access to device agents, read/write access, read/write/all (which allows the modification of device settings), and trap (trap messages are warnings of problems sent by agents on managed devices) (Beckenhauer 2002). Given the dangers inherent in writing and modification, many firms only set the read-only community string, and many products only set the read-only community string by default.

Only in version 3 (www.snmpwalk.com/snmpv3.html) did security get built into SNMP extensively. Version 3 offered confidentiality (optional), message-by-message authentication, message integrity, and time stamps to guard against replay attacks. It also offers the possibility of giving different devices different access to MIB (management information base) data based on security restrictions.

Unfortunately, SNMPv3 authentication and message integrity is based on HMACs, which require the network administrator to know a secret bit string that is different for each managed device. This difficult situation could be alleviated if the standard specified the use of digital certificates for managers. Authentication and integrity would then only require that managed devices know the manager's public key, and there is no problem with shared public keys. In addition, public key encryption would allow the secure exchange of symmetric keys for bulk encryption for confidentiality. However, the large number of devices involved and the desire to keep processing loads on managed devices low (public key encryption is highly processing-intensive) has made public key authentication and integrity unattractive to standards makers.

For more information about SNMP security, read Blumenthal and Wijnen (1998).

LDAP

Increasingly, companies store security information and other critical corporate information in central repositories called directory servers. To query data in a directory server, devices commonly use the lightweight directory access protocol (LDAP), which governs search request and responses.

The IETF has long understood the importance of creating good security for LDAP in light of the extreme

importance of information contained in the directory. The core security focus of LDAP must be authentication because successful impostors could learn large amounts of damaging information about a firm if they could get wide access to this data by claiming to be a party with broad authorization to retrieve data. They could also do extensive damage by "poisoning" the directory with bad data.

The first version of the standard, LDAPv1, had no security. LDAPv2 provided authentication options for the first time. It permitted initial anonymous, simple, and Kerberos 4 authentication. All of these were fairly weak. In 2006, the IETF extended LDAP security through a flurry of security-focused LDAP RFCs.

LDAPv3 also supports the simple authentication security layer (SASL) (Myers 1997). This method allows the searcher and the directory server to authenticate each other in several ways, including Kerberos 5, HMACs, and external authentication. External authentication means that the parties can do authentication any way they want, essentially taking authentication outside the LDAP process. For instance, if the searcher and directory server create an SSL/TLS connection at the transport layer, the authentication that takes place at that layer may be sufficient. SASL is extremely flexible, but companies using it must ensure that a sufficiently strong authentication option is selected. Later, LDAP security was extended considerably. This included the use of public key authentication for initial authentication in 2006.

LDAPv3 makes encryption for confidentiality optional. This may seem odd, but many firms use SSL/TLS at the transport layer to protect LDAP traffic. SSL/TLS does encryption for confidentiality, and many firms feel that also encrypting LDAP traffic at the application layer as well would be needlessly expensive.

Address Resolution Protocol (ARP)

When a router receives a packet, it looks at the packet's destination IP address. Based on this destination IP address, the router sends the packet back out another interface (port), to the destination host or to a next-hop router (NHR) that will next handle the packet. We will use the term "target" for the destination host or NHR.

The destination IP address in the packet gives the target's IP address. However, to deliver the packet, the router must encapsulate the packet in a data link layer frame and deliver the frame to the target. This requires the router to know the data link layer address of the target, for instance, the target's Ethernet MAC (media access control) address.

If the router does not know the target's data link layer address on an Ethernet network, the router must use the address resolution protocol (ARP) (Wahl, Howes, and Kille 1997). The router first broadcasts an ARP request message to all hosts on the subnet connected to the port out of which the packet is to be sent. In an Ethernet network, the broadcast MAC destination address is forty-eight 1s. Switches on the subnet will deliver frames with this address to all hosts on the subnet. All hosts on the subnet, furthermore, will accept frames with all-1s destination addresses.

Within a broadcast frame, the router sends an ARP request message. The ARP request message contains the IP address of the target. All hosts except the target ignore this message. The target, however, recognizes its IP address and sends an ARP reply message back to the router. This message tells the router the target's data link layer address.

Now that the router knows the target's data link layer address, the router takes the IP packet it has been holding and places it in a frame with the target's data link layer address in the destination address field. The router sends this frame to the target.

To handle future packets to the same destination IP address, the router also places the target's IP address and data link layer address in the router's ARP cache. When the next packet addressed to this IP address arrives, the router will not have to do ARP. It will simply look up the data link layer address in the ARP cache.

The ARP assumes that all hosts are trustworthy. However, an attacker host can use this trust to make an attack. Specifically, an attacker's host can send ARP reply messages with the attacker's data link layer address and all possible IP addresses on its subnet. Due to the fact that ARP is stateless, routers should accept ARP response messages even if the router did not send an ARP request message. This approach will poison the ARP cache, causing the router to send all messages intended for most hosts on the subnet to be sent to the attacker.

In some cases, after reading frames, the attacker passes them on to the intended destination host. It may also be able to relay traffic going in the opposite direction. In this man-in-the-middle attack, the two sides are unaware that their traffic is being read and perhaps added to.

The widely available `arpsniff` program implements a man-in-the-middle attack with extreme ease. However, the computer in the middle has to be on the same broadcast or ring subnet as the other two communicating partners for it to work. This makes ARP spoofing difficult to implement. However, if a computer on a subnet is hacked remotely, the attacker does not have to be on the victims' subnet.

Currently, there are only preliminary efforts within the IETF to add authentication to the ARP, under the ARPsec label.

ARP only works on Ethernet and other broadcast networks. Other protocols for finding host data link layer addresses associated with IP addresses are used for other types of nonbroadcast network technologies. These generally suffer the same security exposures that ARP does.

Dynamic Host Communication Protocol (DHCP)

It is possible to manually configure a client PC by typing in its IP address and other configuration parameters needed to communicate over the Internet or a corporate internet. Servers typically are configured manually. However, client PCs normally are configured automatically by getting these configuration parameters from a dynamic host configuration protocol (DHCP) host (Droms 1997).

When a client PC boots up, it realizes that it has no IP address. It broadcasts a DHCPDISCOVER message to learn what DHCP servers are reachable. Each DHCP server that receives the discover message sends back a DHCPOFFER message that gives an offer specifying what IP address it will provide, a lease time (how long the client may keep the IP address), and other configuration information.

The client PC selects one offer and sends a DHCPREQUEST to the selected server. The DHCP server sends back a DHCPACK message acknowledging the acceptance and providing configuration parameters, including an IP address, subnet masks, DNS addresses, and other information. The client PC is now configured.

DHCP is built on connectionless UDP, which makes adding security difficult in general. More specifically, DHCP does not authenticate the client or the DHCP server, and this allows several possible attacks. For an example, an attacker posing as a client PC can repeatedly request DHCP service, each time accepting an IP address. Within a few seconds, the DHCP server will be drained of available IP addresses. If a legitimate client then requests configuration service, it will not be able to get an IP address and so will not be able to use the Internet or an internal corporate internet.

The attacker also can impersonate a DHCP server. The attacker will then respond to all DHCPDISCOVER messages with a very attractive offer (long lease duration and so forth). If a client accepts this configuration information, this information may cause the client to send packets that cannot be delivered or to act in other ways that harm itself or other hosts.

The IETF is now working on DHCP authentication. RFC 3118 (Droms and Arbaugh 2001), which defines two authentication options for DHCP. The first involves a key that is shared by the client PC and by the DHCP server. This key, however, is transmitted in the clear. This easily-read transmission approach is only useful for protecting the client against a host that *accidentally* installed a DHCP server.

The second option requires each client to use a pair-shared secret key with each DHCP server. Only the DHCP server and the client will know this key. The client and server use this pair-shared secret to add a key-hashed message authentication code (HMAC) to each message. If companies adopt this option, they can have fairly strong authentication, although the authentication will not be as strong as it would be if digital signatures and digital certificates were used.

Dynamic Routing Protocols

Operation. When a packet arrives at a router, the router compares the packet's destination IP address with the rows in its routing table. Each row represents a route to a subnet, network, or larger cluster of IP addresses that contains the destination IP address. The router finds all matches, selects the best match, and sends the packet back out according to instructions found in the best-match row.

How do routers get the information in their routing table? Quite simply, they talk to each other frequently, exchanging data on what they know, especially about recent changes. This communication is governed by dynamic routing protocols. These protocols specify both message exchanges and the types of information that will be exchanged.

Security Concerns. Dynamic routing protocols are dangerous because spoofed messages can seriously poison routing tables and therefore can cause routers to black hole or misdeliver most or all traffic. They can even cause a router to deliver all packets to a single target destination, creating an intense DoS attack. Unfortunately, dynamic routing protocols traditionally have not used cryptographic authentication or other protections.

IETF Efforts. Several routing protocols are in common use, including OSPF (open shortest path first), BGP, EIGRP (enhanced interior gateway routing protocol), and IS-IS (intermediate system to intermediate system). Historically, each of these standards evolved separately, including security features. Today, however, the IETF has a working group on Routing Protocol Security Requirements (rpsec). As we will see, all current IETF routing protocols at least have HMAC authentication.

RIP. For communication within small firms, the IETF created a simple routing protocol called the routing information protocol (RIP). Due to its simplicity, RIP has three main constraints (Panko 2004).

First, RIP selects routes on the basis of the number of hops between routers to get to a destination network or subnet. Selecting the route with the least number of hops generally works well in simple networks but works poorly in large networks. Large networks usually have a mix of LAN and WAN links with widely different costs and speeds. Sending data over a WAN link is much more expensive than sending data over a LAN link, but RIP does not consider these costs or other factors.

Second, RIP only works in networks with a maximum of sixteen hops. In effect, it can only count to sixteen because its hop count field only has four bits. Again, this is not a problem in small networks.

Third, RIP does not scale well. Every minute or so, depending on configuration parameters, each router broadcasts its routing table to all routers on its subnet and also to all hosts on its subnet. With large routing tables, the disruptions caused by this intrusive broadcasting would create serious host and network performance problems. Again, however, RIP is for small networks.

Just as it has a simple general design, RIP initially had no security. RIPv2 (Malkin 1998), however, brought RIP

security up to date. Most notably, RIPv2 has three authentication modes:

- *Null authentication (RFC 1583):* No authentication at all.
- *Simple password authentication (RFC 1583):* The password is sent in the clear in every packet. This method is useful for systems that are accidentally set up as RIP routers.
- *MD5 HMAC authentication (RFC 2328):* This method uses HMACs. RIP broadcasts to all other routers out each interface, so all routers connected to a subnet must share the same subnet secret. Looked at another way, a router must have a different secret on each interface.

As in most other standards, there is no digital signature authentication. RIPv2 does have HMAC authentication, but this uses a community secret compared to a pair-shared secret.

The rpsec's publications discuss other problems with RIPv2's authentication and various ways to address them.

OSPF. For larger networks, most firms use the open shortest path first (OSPF) dynamic routing protocol. This is a more sophisticated protocol for three reasons (Panko 2004). First, it gives routers richer information about possible routes, so that routers can select best-match rows with greater effectiveness. Second, OSPF can serve large networks. Third, OSPF scales well because it only sends messages when there are changes and because selected area routers can centralize communication in a hub-and-spoke topology instead of sending messages in a dense mesh. OSPF should be used in all but the simplest networks.

OSPFv2 (Moy 1998) has the same authentication options as RIP. This includes the weakness of using group-shared HMAC secrets among all OSPF routers in an area. Jones and Le Moigne (2004) discuss other security vulnerabilities in OSPF. These vulnerabilities can lead to some attacks even if HMAC authentication is used. OSPFv3 is used with IPv3.

BGP. Both RIP and OSPF are interior dynamic routing protocols that are only used within the networks of individual corporations. However, firms need an exterior dynamic routing protocol to communicate with their ISP's router. In addition, ISPs need an exterior dynamic routing protocol to communicate with one another.

On the Internet, a single exterior dynamic routing protocol is dominant: the border gateway protocol (BGP). *Gateway* is the old term for *router*, so BGP is a protocol for communication between border routers at the edges of their networks.

Richard Clarke, former National Coordinator for Security, Infrastructure Protection, and Counter-Terrorism for the President of the United States, has labeled BGP as one of the two greatest dangers on the Internet. As noted earlier, Clarke's other nomination is DNS. DNS is dangerous because it potentially could be forced to redirect all Internet traffic in harmful ways. BGP is dangerous

because if it is compromised, traffic over the Internet could be redirected in harmful ways by the routers that actually move traffic. The DNS danger is like vandals removing or switching around road signs. The BGP danger is like vandals blowing up bridges.

The most recent version of BGP, BGPv4 (Rekhter and Lo 1995), has been in use for more than a decade and is used almost universally on the Internet, although it was updated several times in 2006, especially in RFC 4271.

Despite its critical importance to the Internet, BGPv4 has no cryptographic security at all. However, BGP runs over TCP on port 179, and a large number of BGP users employ an authentication mechanism in TCP (Stewart 1999). This mechanism, described in RFC 2385 (Heffernan 1998), uses a pair-shared HMAC using MD5 (message digest algorithm 5) (although the RFC calls it an MD5 digital signature). If a BGP message is contained in a TCP segment with an improper HMAC, the transport layer discards the message before BGP even sees it.

Dialogues protected with MD5 HMACs are difficult to hijack. Attackers must not only guess TCP sequence numbers, but they must also guess or learn the secret shared by the two routers being connected via TCP.

For stronger security, the two routers exchanging BGP messages can connect via IPsec with at least initial public key authentication. They could also connect via SSL/TLS. In either case, the two routers would need to have public and private keys. In addition, the routers would have to be fast enough to handle the large amount of additional work needed for IPsec or SSL/TLS. This approach does not work for other routing protocols, which use broadcasting (RIP) or multicasting (OSPF).

BGP routers have many options, which have varying levels of security and vulnerability. Windowsecurity.com (2002) has developed a template for securing BGP on the Cisco routers that dominate corporate and Internet use.

In 2006, RFC 4278 formally proposed to allow BGP to continue using weak security methods while a fuller analysis was done on BGP security. It was argued that in BGP's limited environment, external threats were weak enough to justify the continuation of weak security.

EIGRP and IS-IS. There are two other dynamic routing protocols to mention. For interior routing, many firms use Cisco's proprietary EIGRP interior dynamic routing protocol, which can handle the packets of multiple standards architectures in an integrated way. (RIP and OSPF are limited to IP packets.) In addition, OSI offers IS-IS, which would at least provide security by obscurity (not recommended). However, this chapter is about Internet security standards, and Internet transmission requires IP transmission.

Dynamic Routing Protocol Security: Perspective. To date, the focus on dynamic routing protocol security has been authentication. Unless IPsec or SSL/TLS are used to transmit BGPv4 messages, the highest level of authentication for BGPv4 is MD5 HMACs with pair-shared secrets. In addition, for interior routing, the highest level of security for RIP and OSPF is MD5 HMACs with group-shared secrets.

Another issue is that authentication assumes trust. If an attacker gets inside an organization managing a router

or somehow compromises a router, they will be able to send poisoned routing information to other routers, and these other routers are likely to trust the information.

One way to reduce the danger of spurious trust is to block all incoming packets containing dynamic routing protocol information at the firm's border firewall—or at least, to limit incoming packets containing such information to one or two specific external routers.

Application Layer Standards

To users, the Internet is attractive because of its application standards for the WWW, e-mail, and other popular services. While decent security is present for some application standards, many application standards continue to have only weak security—if they have any at all.

Hypertext Transfer Protocol (HTTP) over SSL/TLS

To communicate with a WWW server, a browser uses HTTP version 1.1 (Fielding et al. 1999). HTTP is a simple protocol that offers no security by itself. However, all browser and WWW server programs support SSL/TLS security, and the use of SSL/TLS in e-commerce applications and other sensitive applications is overwhelming. HTTP over SSL/TLS uses port 443 rather than HTTP's normal port 80.

SSL/TLS allows both the browser and the Web server to authenticate each other using digital signatures and digital certificates. However, only the server is *required* to use a digital signature to authenticate itself. This is done because few PCs running browsers have digital certificates. Obviously, not requiring client authentication is a serious problem for protecting Web servers against attack.

E-Mail Security

Security for e-mail is perhaps the great scandal in IETF history. Competing cliques within the IETF have consistently simply refused to cooperate in selecting security standards for e-mail. Consequently, companies that want to implement e-mail security have to use a nonstandard method to do so.

Not surprisingly, sending application layer e-mail traffic over a secure SSL/TLS transport connection is the most popular way to secure e-mail in organizations today. SSL/TLS is well understood, offers consumer-grade security, and has been widely used for HTTP security for several years. Most e-mail programs support SSL/TLS security. SSL/TLS only encrypts e-mail between clients and e-mail servers, not all the way between clients. This only requires a digital certificate on the mail server. However, it requires trust in the e-mail server and in downstream parts of the system (other clients, mail servers, and Internet links).

Another approach, S/MIME (Ramsdell 1999) encrypts e-mail all the way between two clients. This provides end-to-end security. However, it also prevents e-mail servers and firewalls from scanning e-mail messages for malware, and it requires each client to have a digital certificate.

A third approach, pretty good privacy (PGP) (Atkins, Stallings, and Zimmerman 1996), is used primarily by

individuals. Organizations have tended to stay away from PGP because PGP uses user-based transitive trust. (If User A trusts User B, and if User B trusts User C, User A may trust User C.) As noted earlier, this is not a good security policy. If a single user mistakenly trusts an impostor, others may unwittingly trust the impostor as well. PGP by itself is a commercial product. Many mail programs actually implement the OpenPGP standard.

Remote Access Protocols: Telnet, Rlogin, Rsh, and SSH

The first ARPANET (Advanced Research Projects Agency Network) application was Telnet (Postel and Reynolds 1983), which allows a user to log into a remote computer and execute commands there as if the user was a local user. This allows ordinary users to access remote services. It also allows system administrators to manage servers and routers remotely. This use of remote administration is attractive, but it must be done carefully or hackers will end up “managing” corporate servers and routers.

Unfortunately, Telnet has poor security. For example, Telnet does not encrypt host usernames and passwords. Sniffers can intercept usernames and passwords, allowing hackers to log in as these users with all of the privileges of these users.

Telnet should never be used for remote administration because hackers intercepting root passwords would be able to execute any commands on the compromised machine. Telnet is not alone in this respect. In the UNIX world, rlogin and rsh do not even require passwords to gain access to a computer, although other conditions must apply.

For remote administration, some organizations turn to the secure socket shell (SSH) protocol, which offers good authentication, integrity, and authentication (Ylonen et al. 2002). Unfortunately, SSH version 1 had security flaws, and although these have been fixed in SSH version 2, some version 2 implementations will also permit version 1 connections, thus leaving the system open to attack. In 2006, the IETF began an intensive effort to improve SSH security.

File Transfer Protocol (FTP) and Trivial File Transfer Protocol (TFTP)

Another early ARPANET service that continues to be popular on the Internet is file transfer protocol (FTP) (Postel and Reynolds 1985), which allows a user to download files from a remote computer to his or her local computer and sometimes to upload files from his or her local computer to the remote computer. Unfortunately, FTP also sends usernames and passwords in the clear, making it very dangerous. In addition, while the use of Telnet has declined to the point where quite a few companies simply stop all Telnet traffic at their firewalls, FTP is still widely used. The FTPEXT Working Group is considering security for FTP. In addition, FTP can be protected by sending it over SSL/TLS if the FTP program allows this.

FTP has a simpler sibling, the trivial file transfer protocol (TFTP) (Sollins 1992). TFTP does not even require usernames and passwords, making it a darling of hackers who often use TFTP after taking over a computer to download their rootkits (collections of hacker programs) to automate their exploitation of the computer they now “own.”

Web Services

An important emerging application class is Web services. Web service protocols allow programs on different computers to interact in a standardized way. Web services are creating a new level of interoperability between programs on different computers.

The figure shows that Web service interactions often are “chained,” meaning that a single Web service message may initiate a series of other Web service messages.

Web services have only been operational since about 2000, and Web services standards are still rather embryonic. The three main Web service standards are SOAP (simple object access protocol), which governs the format of messages, UDDI (universal description, discovery, and integration), which is like a yellow pages and white pages for finding Web services relevant to a firm’s need, and WSDL (Web Services Description Language), which tells a firm exactly how to work with a specific Web service. However, many other standards need to be set before Web services can be used with confidence.

As in many other applications, security was an afterthought for Web services standardization. Consequently, Web service security standards are even more embryonic than Web service standards in general. Worse yet, Web service security standards have suffered from conflicts among vendors.

The initial security standards for Web services (SOAP, UDDI, and WSDL) were created by the World Wide Web Consortium (W3C). However, Microsoft, which had been a major driving force behind the first three standards, pulled its support from W3C. Rumor suggests that Microsoft did this because W3C only creates standards if the technology is not encumbered by patents (Koch 2003). Microsoft, according to the rumor, wanted to preserve its intellectual property rights.

Whatever its motivation, Microsoft and its main partners, IBM and VeriSign, moved their standards development efforts to OASIS (the Organization for the Advancement of Structured Information Standards). Their efforts were based on the Microsoft/IBM/VeriSign standards efforts called WS- (because all standards begin with WS and a dash).

Sun Microsystems and its allies initially supported a different family of standards, ebXML. In fact, it has been suggested that the IETF gave the WS- standards a cold reception at the 2000 IETF meeting because Sun had the chair role (Newcomer 2003). However, when the ebXML effort fell apart, Sun threw its weight behind the WS-standards efforts at OASIS.

To confuse matters even further, Microsoft and its allies created a new standards organization, WS-I, where the I stands for interoperability. Initially, WS-I’s purpose is to develop implementation profiles built from various Web services standards. Sun was excluded from WS-I but was eventually allowed to join as a board member.

In 2004, there was a major breakthrough when OASIS ratified the WS-Security standard submitted by Microsoft, IBM, and VeriSign in 2002. WS-Security, in a move toward openness, adopted several standards from W3C, including standards for encryption and digital signatures. In the near future, WS-Security should be extended to work with the OASIS SAML (Security Assertions Markup

Language) standard, which specifies how organizations can exchange authentication information.

Unfortunately, WS-Security is only part of the framework created for Web service security by Microsoft, IBM, and VeriSign. To be effective, six more elements are needed: WS-Policy, WS-Trust, WS-Privacy, WS-Secure Conversation, WS-Federation, and WS-Authorization. Microsoft and its allies have not submitted these additional elements to OASIS, making the standardization of WS-Security a limited development.

Authentication is a complex issue for Web services standards. WS-Security does not have complete authentication, and Sun and its partners have developed a major authentication system under the auspices of the Sun-led Liberty Alliance. Although Sun has endorsed the Microsoft standards efforts, Microsoft has not done the same for the Liberty Alliance standards, probably because Microsoft has a competing authentication product, Passport.

Especially interesting aspects of the W3C standards are its XML Encryption and XML Signature standards, which are part of WS-Security. Obviously, these standards provide for encryption for confidentiality and digital signing. What makes them interesting is not their cryptographic methods but the fact that they can be applied to *parts* of a message as well as to the entire message. The capability to encrypt and sign parts of messages is important because some Web service messages go to more than one party, and only some parts of the message are relevant to (or should be read by) each party.

Web services security protocols have a long way to go before they are ready for use with confidence. In addition, the protocols that do exist still are subject to DoS attacks and other dangers.

However, if a Web service interaction will only take place between two parties, it may be sufficient to protect and authenticate the communication using SSL/TLS. However, not having protection and authentication *within* messages via XML Encryption and XML Signature leaves Web services open to certain attacks.

Other Applications

There are many other Internet applications, and their standards vary widely in their degree of security. VoIP (voice over IP) security is a particularly sensitive emerging standards application issue. In addition, database applications and many other applications are not even standards-based.

Unfortunately, many operating system installations automatically turn on quite a few applications without the knowledge of the systems administrators or users. For example, when SNMP vulnerabilities were found in 2002, it was discovered that many vulnerable machines should not have been running SNMP at all. An important rule in hardening clients and servers against attack is to turn off all applications that are not absolutely needed to run the computer.

CONCLUSION: THE STATE OF INTERNET SECURITY STANDARDS

Today, if two communication partners want to communicate securely, they can do so by adding dialogue

security on top of the nonsecure Internet transmission. For lightweight needs, they can turn to PPTP or SSL/TLS. For industrial-strength security, they can use IPsec.

General Insecurity

More generally, however, under the Danvers Doctrine, the standards that the Internet needs for message delivery (IP, TCP, and UDP), Internet supervisory standards (ICMP, DNS, SNMP, LDAP, etc.), and Internet application standards (WWW, e-mail, etc.) vary widely in security from none to semi-adequate. Consequently, the Internet today is rather fragile and open to seriously damaging attacks. Given the pace of security implementation in individual standards, the fragility of the Internet is not likely to change radically in the next two or three years. Even after more secure standards are developed, it will take several years for them to be widely adopted.

The Broad IETF Program

At the same time, there is an extremely broad concern with security across the IETF. Although some standards have better security than others, standards working groups appear to be playing leapfrog in their efforts to improve security across a broad spectrum of Internet standards.

The Authentication Problem

Digital Certificates

The most difficult problem in Internet security standards is authentication. Most Internet standards today from the IETF offer a maximum of HMAC message-by-message authentication.

However, unless authentication uses public key authentication (such as digital signatures) coupled with digital certificates managed by a reliable and well-regulated network of CAs, authentication strength will only be moderate. However, creating large public key infrastructures will take years, and while European countries are moving to manage and regulate CAs, the United States has adopted the let-the-market-do-it philosophy that has worked so well recently in the energy industry and in corporate financial reporting.

One option is to use public key authentication with digital certificates and then use HMACs for message-by-message authentication. Although this would lose non-repudiation for individual messages, it would decrease the processing intensiveness of VPNs and other CPSs. However, this still requires an infrastructure for managing public/private key pairs and digital certificates.

Distributed Authentication

Another problem is distributed authentication. There is unlikely to be a single global authentication authority. Consequently, multiple authentication authorities must be able to work together. Most importantly, there must be mechanisms for implementing transitive trust, in which an authentication authority trusts credentials provided by another authentication authority. In public key authentication, there has long been the concept of a hierarchy of certificate authorities, but no single CA tree is likely to emerge across the world.

More federated one-to-one and one-to-few horizontal trust systems are now under development, especially for Web services. These include the Liberty Alliance, IBM and Microsoft (WS-* security) standards, and OASIS standards.

The Primary Authentication Problem

One broad and deep problem in authentication is the primary authentication problem—proving the identity of a person or organization in the first place, say to give them a digital certificate or accept them as an employee. Identity theft has long allowed impostors to obtain fraudulent drivers' licenses and other authentication instruments. Even within closed systems, such as corporate networks, the prime authentication problem can be daunting. For consumer authentication and other large communities, the technical and operational problems for credible initial authentication are extremely daunting.

Protection from Denial-of-Service (DoS) Attacks

One security threat that has barely been faced so far is the prospect of DoS attacks. Although a few standards have taken some steps to reduce DoS attack risks, this is an area of little general development within the IETF.

Internet Forensics Standards

One area that we did not look at in this chapter is standards to make the Internet forensic, that is, able to collect and analyze traffic data in a way that would make the prosecution of attacks possible. Without forensics standards, it will continue to be nearly impossible to find and prosecute attackers.

The IETF to date has shown no interest in developing forensics standards. In fact, in 1999, the IETF polled its members about whether the IETF should develop protocols to support law enforcement requirements for wiretapping voice conversations carried over the Internet. There was a strong preponderance of comments against developing standards for implementing wiretapping (Macavinta 1999).

GLOSSARY

Community Key or Community Secret: Secret shared by multiple devices within a network.

Cryptographic Protection System (CPS): Standards-based system for automatically providing multiple protections in a dialogue between two parties.

Danvers Doctrine: An IETF decision to add security to all or nearly all TCP/IP protocols.

Denial-of-Service (DoS) Attacks: Attacks that attempt to render a computer or network useless to its user; not addressed in most Internet security efforts.

Dialogue: The transmission of multiple messages in both directions between two hosts.

Dialogue Security: Security applied to a dialogue (ongoing message exchange between two parties); often added on top of nonsecure Internet transmission.

Digital Signature: Message-by-message authentication system based on public key encryption. To work very

well, the parties should have digital certificates from trusted certificate authorities.

Dynamic Routing Protocol: A protocol that routers use to communicate with one another to exchange information for their routing tables.

HMAC: See Key-Hashed Message Authentication Code.

Internet Engineering Task Force (IETF): The body that creates TCP/IP standards for the Internet. Now engaged in a broad effort to add security to Internet standards.

In the Clear: When a message is transmitted without encryption for confidentiality or other cryptographic protections.

IPsec: Family of standards for adding security to both IPv4 and IPv6 transmission dialogues.

Kerberos Server: Authentication system in which a central server gives out authentication and authorization information.

Key-Hashed Message Authentication Code (HMAC): Message-by-message authentication system based on a secret key shared by two parties.

Multilayer Security: Providing security at multiple standards layers in order to provide defense in depth.

Password Authentication: Authentication in which the two sides know a password consisting of keyboard characters.

Point-to-Point Protocol (PPP): Secure protocol for communicating over a point-to-point data link.

Point-to-Point Tunneling Protocol (PPTP): Protocol that extends PPP transmissions over an internet; extends PPP security over the route.

Policy Server: In a security system, a server that tells devices how they must implement security.

Remote Authentication Dial-On User Service (RADIUS) server: A server that stores authentication data so that access servers can apply authentication criteria consistently.

Remote Access Server (RAS): Security server at a site that terminates and manages a PPP connection or PPTP connection over the Internet.

Secure Sockets Layer (SSL)/Transport Layer Security (TLS): General standard for adding security to the transport layer. Formerly called Secure Sockets Layer (SSL) and still widely known by that name. Also called HTTPS because URLs beginning with "https" are requesting SSL/TLS security.

Virtual Private Network (VPN): Family of standards for adding security to a dialogue over an untrusted network, most commonly the Internet. Includes PPTP, IPsec, and SSL/TLS.

INTRODUCTION

Speech coding is about representing a speech signal with as few bits as possible provided that only acceptable distortion is introduced when the speech signal is reconstructed from the bit stream. Or else, given a bit rate, the speech coder designed for lowest distortion is sought. In actual practice, other requirements have to be satisfied. A certain product may be envisaged, imposing requirements on power consumption and restricting the possibilities for processor selection and memory resources that will be made available. Even when a powerful processor is available in a media gateway, for instance, system resources may have to be shared among a large number of simultaneous users.

For two-party communications, which is the rule for vocoding, delay has to be constrained so that dialog conditions may prevail. This may restrict coder delay depending on the communication links between encoder and decoder. Moreover, in the recent and expanding domain of packet communications, variable delay must be tolerated and the coder must behave nicely when packets get lost or are delayed on their way. This adds requirements of robustness on top of usual care for single-bit error correction and frame erasure concealment. The latter mostly affects wireless communications.

Speech-coding techniques range from companded (compressing-expanding law) sample quantization in pulse code modulation (PCM) and differential signal coding with adaptive quantization in differential PCM (DPCM) to differential signal coding with additional adaptive prediction in adaptive DPCM (ADPCM) for waveform coders. These techniques are directly linked in the text to ITU-T (Telecommunication Standardization Sector of the International Telecommunication Union) recommendations for wireline telephony, which are the strictest in requirements of speech quality and communication links or tandeming between communicating parties.

Next, the important set of linear prediction (LP) techniques is introduced in a parametric vocoding context. This paves the way to the discussion of code-excited LP

(CELP) coding with its important notions of an analysis-by-synthesis loop and an excitation search driven by the speech signal reconstruction error. In the ITU-T evolution line, the introduction of a CELP coding recommendation marks the overcoming of a resistance to the acceptance of a delayed speech coder, albeit to a moderate degree, with the adoption of low-delay CELP (LD-CELP). In addition, the increment in coder complexity prompts the adoption of a new style of “executable” standards where a reference coder implementation in C language comes along with the classical written recommendation. Eventually, a bit-exact fixed-point reference implementation is provided.

In general, an ITU-T speech-coding project goes through the following phases:

- Establishment of the Terms of Reference.
- Selection of one candidate. If more than one candidate fulfill the requirements, then a compromise solution is found.
- Optimization of the selected candidate.
- Characterization.

Evolutions in speech coding were adopted after intensive tests in the next recommendation for vocoding at 8 kbit/s by means of conjugate-structure algebraic CELP (CS-ACELP) with its capability of both delivering high-quality speech and allowing for efficient search algorithms. This combination of features, besides fulfilling the ITU-T requirements for certain types of multimedia communications over wireline telephone connections, has prompted a wave of new digital cellular standards for operation at 8 kbit/s and below and even for operation at variable bit rate.

New developments of CELP coding in its combination with parametric coding, mainly for variable bit rate mobile and packet communications, including wideband codecs, are outlined as well as the move of parametric vocoding to higher-quality speech coders in secure communications, albeit without reaching strict toll quality. Also, as a guide to techniques that may eventually play important

roles in the development of future speech coding standards, sinusoidal coding and waveform interpolation (WI) techniques are presented in connection with research topics in speech analysis and very low-bit-rate vocoders.

SPEECH CODER ATTRIBUTES

Speech coders are supposed to provide a compact representation of the speech signal from which it can be reconstructed. Therefore, bit rate and distortion are important attributes in the design and selection of a speech coder. Additionally, complexity is an important issue in the design and portability of the codec, and delay is a characteristic that impacts its applications over communication channels.

Bit Rate and Distortion

A speech coder may be functionally divided into an encoder and a decoder. The encoder analyzes the speech signal $s(n)$ whose relevant features are encoded into the bit stream $c(n)$, to be transmitted through the channel to the decoder as shown in Figure 1. In turn, on its propagation through the channel, a distorted bit stream $c'(n)$ reaches the decoder, which decodes it and delivers a reconstructed speech signal $\tilde{s}(n)$.

As an input to the coder, the speech signal is supposed to be given by a sequence of samples. Table 1 provides a description of various classes of speech and audio signals, relating their bandwidths, sampling rates, amplitude resolution, and bit rates. This chapter will be mostly concerned with narrowband (NB) and wideband (WB) speech signals.

The speech encoder is supposed to represent the speech signal by a set of parameters, which in turn it codes into codewords whose bits are joined and transmitted sequentially. This output binary signal is the bit stream, and the bit rate, usually measured in bit/s, is just its rate of binary symbols. In rate-distortion theory, the rate is usually measured in bits per sample of the original signal waveform (Jayant and Noll 1984).

Rate and distortion are inextricably related. The most popular measure related to distortion is the signal-to-noise

ratio (SNR). Actually, the SNR is a measure of similarity or fidelity, which is the reciprocal ratio or the reverse of a distortion depending on whether SNR is measured as a linear ratio or logarithmically in decibels (dB). As a matter of fact, we should say signal-to-quantization-error ratio instead of SNR as no actual noise is involved in the process of coding, but the treatment of quantization error as a noise source has proven a very powerful mathematical construct.

In lossy coding, if the rate is increased while keeping other conditions constant, distortion may not increase and is likely to decrease. That is, rate and distortion vary inversely. When quality is measured instead of distortion, a rate increase is likely to cause an increase in quality as shown for two complexity levels in Figure 2, where subjective quality is measured by the mean opinion score (MOS) explained next. The relative positions of some selected standard coders in this figure should be considered indicative only because the data have been extracted from different tests. In rate-distortion theory, the condition is that, when given a rate, the minimum possible distortion or bound is tabulated for the corresponding distortion. Likewise, given a distortion, the minimum possible rate is assigned as the corresponding rate. But this theory is not concerned with the implementation of the coder that would actually realize that rate for the given distortion or, conversely, that causes that distortion for the given rate. In practice, we have to be concerned with the actual coder at hand. Then, two additional coder attributes come in our way, complexity and delay, as will be discussed in the following subsections.

A meaningful and practical measure of distortion may not be trivial to find or define. Even for waveform coders, the SNR may not reflect adequately our hearing perception because weak signal segments do not influence SNR calculation, which is dominated by the louder segments. This situation is ameliorated by evaluating each SNR over a signal segment in dB and taking an average over the number of segments in the signal. This measure is the segmental SNR (SNRSEG), which is typically evaluated for segments 16 ms long (Jayant and Noll 1984).

Ultimately, subjective opinions collected in listening tests are the most appropriate to assess actual coder performance but are prohibitive while the coder is in development due to the cost and schedule delays incurred. So, objective measures that simulate subjective opinion are an important tool during coder development. There are various methods for subjective testing (ITU-T 1996c; Kroon 1995), but the most widely used is by far the mean

Figure 1: Major blocks for speech coding

Table 1: Bit Rates for Typical Digitization of Audio Signals

Description	Bandwidth	Sampling Frequency	Bits per Sample	Bit Rate
Narrowband (NB) speech	300 Hz–3.4 kHz	8.0 kHz	16	128 kbit/s
Wideband (WB) speech	50 Hz–7.0 kHz	16.0 kHz	16	256 kbit/s
Super-wideband speech	50 Hz–14.0 kHz	32.0 kHz	16	512 kbit/s
Audio (CD format)	10 Hz–20.0 kHz	44.1 kHz	16	706 kbit/s
Audio (DAT format)	10 Hz–20.0 kHz	48.0 kHz	16	768 kbit/s

Figure 2: Subjective quality for narrowband speech coders over a range of bit rates for two illustrative complexity level curves

Table 2: Quality Rating Scales Referred to Quality and Impairment for Use in Absolute Category Rating (ACR) Tests and Degradation Category Rating (DCR) Tests, Respectively

Quality-Based Description	Impairment-Based Description	Quality Rating
Excellent	Imperceptible	5
Good	Perceptible but not annoying	4
Fair	Perceptible and slightly annoying	3
Poor	Annoying but not objectionable	2
Bad	Very annoying or objectionable	1

opinion score (MOS) where each listener is asked to evaluate the whole quality of reconstructed speech absolutely in an adjectival scale that ranges from bad to excellent. Then opinions are mapped to numerical indices from 1 to 5, respectively, and the final MOS is the average of the indices taken over all listeners, talkers, and samples in the test. The description and an illustrative range of MOS rating are displayed in Table 2 and Figure 2, respectively.

The MOS is an absolute category rating (ACR) test where listeners are presented only to a single speech sample at a time. For degradation discrimination, both the original and the degraded speech signal are presented to the listeners in what is called a degradation category rating (DCR) test. Its rating scale is also 5-point but the adjectival descriptions are focused on the perceived degradation as shown in Table 2. A more precise impairment discrimination may be achieved by comparison category rating (CCR) tests where the listeners are asked to identify which stimulus is the original one by means of a two-sided scale as given by Table 3. Also, the modified CCR (Mod CCR) method uses processed reference speech samples but with no noise suppression, whereas the pure CCR method uses unprocessed reference samples. Besides, pair-comparison or A-B preference tests are binary comparison tests where

Table 3: Quality Rating Scales Referred to Relative Quality for Use in Comparison Category Rating (CCR)

Description	Quality Rating

just a preference is asked from the listener. The binary nature of these tests, however, does not preclude the derivation of nonbinary ratings as long as possible coder pairs are compared.

Although it is not wise to dispense with listening tests altogether, the development of objective perceptual measures of speech quality has been fruitful in recent years. Most illustrative of these advancements is the

sequential development of the perceptual speech quality measure (PSQM) (ITU-T 1996d) and the perceptual evaluation of speech quality (PESQ) (ITU-T 2001). Most notably, PESQ measurements correlate well with subjective opinions even when delay and variable delay intervene between the original and the reconstructed signals, although some limitations still apply (ITU-T 2005a, 2005b). In addition, the wideband PESQ (ITU-T 2005d) is intended for wideband codec evaluation but it should be used only for relative rating because its MOS values are much lower than expected (Gibson 2005).

Actually, the PESQ is the first objective measure of speech quality that is capable of testing network impairments (Rix 2004). However, the PESQ is an intrusive measure in the sense that it uses the original signal as a reference. A nonintrusive algorithm for objective quality assessment is provided by the P.563 Recommendation (ITU-T 2004) to be used at network nodes.

Complexity

The operational complexity of a coder implementation is usually considered to involve the processing speed and the read-write memory (RAM) necessary for running variables (Kroon 1995). However, a comprehensive quality measure should also include read-only memory (ROM) for both data and program usage. Fixed-point arithmetic is especially convenient for bit-exact measurements, and its importance accrues as most implementations of speech coders run in mobile devices that are capable of fixed-point arithmetic only for lower power consumption reasons among others.

For a specific digital signal processor (DSP) architecture, the measure of processing speed is million instructions per second (MIPS). But, during algorithmic development, the final DSP to be chosen is not usually known; in fact, various platforms may be contemplated in the development of a reference coder for a standard, for instance. Therefore, the important step has been taken by ETSI to establish a virtual basic DSP for speech coding through a library of basic operations (BASOPs) to be used in simulated fixed-point C language speech coder implementations. Extensions to this library have been made available by ITU-T through Recommendation G.191 on "Software Tools for Speech and Audio Coding Standards." Each BASOP has an individual complexity weight, which is unity for simple operations like addition, multiplication, and multiply-accumulate (MAC) and is correspondingly larger for more complex operations. The per-second average operation count obtained in a statistically significant coding session is the weighted million operations per second (WMOPS) measure.

This primary set of basic operators uses 16- and 32-bit variables and a 32-bit accumulator. More recently, an alternative set of basic operators with a 40-bit accumulator has been developed for use in 3GPP2 and standardized in the 2005 revision of ITU-T G.191 (STL2005).

Delay

Delay or the time lag between the production and reception of sound is the attribute of a speech coder that may

have the most disruptive effect on interactive communication. Nonetheless, for VoIP, it is reported that in a conversation, packet losses are a more severe impairment than delay (James, Bing Vhen, and Garrison 2004).

For the design and deployment of speech communication systems, it is important to break down the total delay into components that may be attributed to functional system elements. An inherent component of delay is called *algorithmic delay*, which comes about as a consequence of signal acquisition and buffering and is directly related to block length. Sometimes algorithmic delay has to include look-ahead buffering, which may be used for smoothing the evolution of some coder parameters such as pitch and in the analysis of short-term LP coefficients. However efficient the implementation, algorithmic delay is irreducible because it is an attribute of the algorithms used themselves, the processor notwithstanding.

Another component of delay is actual signal processing, which is the time it takes the processor to analyze the buffered signal to be encoded and to reconstruct the signal from the decoded parameters. This component depends on the processing speed provided by the processor and memory used. As a major component of delay, algorithmic delay and processing delay are jointly referred to as one-way codec delay (Cox and Kroon 1996).

The third component of delay includes bit stream buffering, multiplexing, and transmission delay. This component depends on propagation and other properties of the channel. In particular, in packet communications, transmission delay is variable and is further decomposed into fixed delay and a jitter. As a general rule of thumb, a rough estimate of delay is three times the frame length plus signal processing delay, including any look-ahead. To enable interactive voice communications, total delay should be below 200 ms in the absence of echoes. If echoes are present, total delay should not exceed 25 ms (Cox and Kroon 1996). This underlines the importance of echo cancellation and the need for low-delay coders in some applications as typified by the G.728 coder in the "Vocoding Standards" section later in this chapter.

In VoIP applications, additional delay occurs because the packet usually contains more than one frame. For instance, G.711 is generally packetized in 10 ms, 20 ms, or even larger blocks.

TRANSMISSION IMPAIRMENTS

The medium across the speech encoder and the speech decoder may harm the bit stream as indicated earlier in Figure 1. In store-and-forward systems, the damage usually affects isolated bits while they are stored. Similarly, in wireline communications, single-bit toggling can occur due to impulse noise. On the other hand, in mobile communications, burst errors usually affect whole frames of code causing frame erasures. Likewise, in packet communications, whole packets may be lost or be received out of order. When a speech coder is tested for a given transmission channel, sensitivity to an error in each bit is evaluated by the magnitude of the degradation incurred, and groups of bits are formed for different sensitivity levels so that even different channel coders may be used for different groups (Steele 1993).

The more complex speech coding standards such as G.728 and G.729 that use CELP models have provisions for frame erasure concealment by extending the application of model parameters for previous good frames to the erased frames. On the other hand, for simple, one codeword per sample coders such as G.711, no model parameters are available for working out any signal extension to bridge across the missing frames. Therefore, the packet loss concealment (PLC) algorithm itself maintains a memory of past samples, organized as pitch periods for voiced speech, which are repeated with progressive attenuation. However, pitch periods may be repeated out of their order of occurrence in the original signal if the loss is rather long. To prevent artificial enhancement of periodicity, the synthetic speech signal is modified. Such a PLC algorithm was recommended as ITU-T Recommendation G.711 Appendix I (09/99) and also in ANSI Standard T1.521-1999 (Cox, Malah, and Kapilow 2004).

For operation in the public switched telephone network (PSTN), a codec should be robust to asynchronous tandem encodings with itself and with other codecs in the network. In this respect, the G.711 codec is remarkable for its MOS will still be above 4.0 after 8 asynchronous tandems with itself, down from an MOS of about 4.4 for a single encoding (Gibson 2005). On the other hand, the G.726 codec drops to an MOS of about 3.0 after 4 asynchronous tandems with itself when for a single encoding an MOS of about 4.0 is obtained.

The connection of two speech codecs usually involves decoding and reencoding, causing a loss of quality. If the codecs use the same technology, a direct mapping of their parameters could be done without ever having to reconstruct the speech signal. This is called intelligent or smart transcoding (Kang, Kim, and Cox 2003).

TECHNIQUES FOR SPEECH CODING

The very basic technique in signal coding is entropy coding, which is lossless; that is, the signal waveform may be exactly recovered from the code sequence or bit stream. In other words, entropy coding exploits only information redundancy in the signal or sample sequence. But the compression ratio that may be attained for speech signals is really low, and lossy coding is always used. The hub of lossy

coding is quantization, which is essentially irreversible. The proper use of this technique will remove only irrelevant information. The definition of irrelevance, to be sure, rests upon human auditory perception. And, actually, approximate loudness discrimination was the feature initially used in speech quantization as mentioned later in the “Vocoding Standards” section.

The quality and efficiency of vocoding rests upon the isolation of irrelevance and the ease or difficulty in its removal. Rather, based on the characteristics of the human speech production process, an efficient collection of methods called linear prediction has been developed that is very effective in isolating much of the redundancy in the speech signal to be extracted during encoding and later reinstated when decoding. Then, anticipating what will happen in the listening process, the coder uses the masking properties of human listening in the identification and removal of irrelevance by proper quantization methods.

Waveform Coding

Waveform coding involves the quantization of some signal or waveform. In its simplest form, the waveform used is the original speech signal, and quantization levels are nonuniformly distributed over the amplitude range. These are said to be PCM (pulse code modulation) coders.

Higher complexity waveform coders use the difference signal $d(n)$ for quantization by an adaptive uniform quantizer. This signal is generated inside a quantizer-predictor loop as the difference between the original speech signal $s(n)$ and the predicted speech signal $\hat{s}(n)$ as represented in Figure 3. Therefore, it is a prediction error signal. Quantizer $Q(\cdot)$ approximates $d(n)$ by its nearest code level $\tilde{d}(n)$, which is added to the predicted speech sample $\hat{s}(n)$ to come up with the reconstructed sample $\tilde{s}(n)$. Finally, the reconstructed sample is input to predictor $P(z)$, which delivers the predicted speech signal $\hat{s}(n)$, so closing the loop.

The predictor may be fixed, and the coder is said to be a differential PCM (DPCM) coder. A special case of DPCM is delta modulation (DM) whose quantizer codes at the rate of 1 bit/sample. In fact, adaptive DM (ADM) has a fixed predictor and an adaptive quantizer, which is generally adapted by either of two algorithms: continuously variable slope delta modulation (CVSD) or the Jayant multiplier algorithm (Jayant and Noll 1984). Actually, it has been widely used by the military and also for avionic

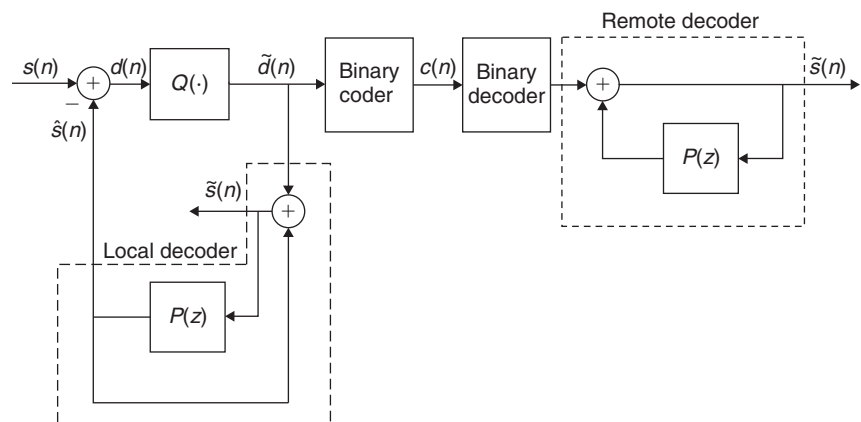

Figure 3: Quantizer-predictor feedback loop in a differential PCM coder and associated decoder

Figure 4: Power spectral density of a voiced speech segment (solid line) extracted at 0.75 s from the signal in Figure 10 and its corresponding 10th-order LP spectral envelope (dashed line)

communications and private communications due to its robustness to transmission errors, low cost, low delay, and low power consumption. However, ADPCM, discussed later, delivers higher-quality speech in error-free conditions (Steele 1993).

For higher performance, the predictor coefficients are adapted on a sample basis for adaptive DPCM (ADPCM) coders or on a block basis for adaptive predictive coders (APCs). In adaptive predictive coding, LP analysis techniques are employed.

Linear Prediction (LP)

The greater part of the redundancy in a speech signal may be represented by an LP model. Its spectral representation is a smoothed version of the speech signal spectrum, corresponding to a kind of spectral envelope as shown in Figure 4 for a voiced speech signal segment also represented by a vertical slice at 0.75 s in Figure 10 later in this chapter, where the gain in the model has been adjusted to match the signal's integrated power spectrum. The remaining fine details in the signal spectrum may be captured as the prediction residual spectrum, whose corresponding waveform is shown in Figure 5.

In the synthesis phase, a coded version of the prediction residual signal feeds the synthesis filter that shapes its spectral envelope. This constitutes a simplified yet powerful model of speech production, schematically represented in Figure 6. In linear predictive coding (LPC), the residual signal is modeled as a linear combination of a periodic pulse train for the periodic or voiced component of speech and a pseudorandom noise sequence for its unvoiced component. A greater simplification of the model consists of using only the major voiced or unvoiced component. For determining the excitation, LP analysis is a very helpful aid for the residual signal waveform displays enhanced peaks as compared to the original speech signal waveform (see Figure 5). Besides, the reader should not be misled by scale normalization and notice that the amplitude range of the residual signal is much lower.

Further analysis of the residual signal waveform in Figure 5 reveals that because it is periodic just as its

Figure 5: Waveform of a voiced speech signal segment (top) extracted at 0.75 s from the signal in Figure 10 and its corresponding 10th-order LP residual signal waveform (bottom)

Figure 6: Source-filter model of speech production where excitation type may be a linear combination of pseudorandom noise or periodic pulses whose fundamental frequency should be further specified. The amplitude of both types of excitation must be adjusted by their weights and common gain factor. Filter coefficients may be controlled

corresponding speech signal segment, it may be linearly predicted as well. In this case, the LP analysis uses an autocorrelation lag range of the order of a pitch period so that the predictor obtained is called a long-term predictor (LTP) as opposed to the sample period predictor

discussed previously, which is called a short-term predictor (STP). Lower prediction orders, such as first- or third order, are more usual for the LTP. The pitch period or pitch lag ranges from about 20 to 147 samples for NB speech and from about 30 to 230 samples for WB speech for a fundamental frequency range from about 55 Hz to 400 Hz. The LTP replaces the LPC pulse generator with advantage because it is less sensitive to pitch detection and can additionally shape the excitation signal.

Linear prediction analysis algorithms usually deliver a set of prediction coefficients a_i , $i = 1, 2, \dots, p$, where p is the prediction order, which define a synthesis filter

$$H(z) = \frac{1}{1 + \sum_{i=1}^p a_i z^{-i}}. \quad (1)$$

Usually, $p = 10$ for most NB codecs. The prediction coefficients are not suitable for quantization because their range can't be easily determined and the stability of the synthesis filter in Eq. (1) cannot be guaranteed when using quantized and interpolated prediction coefficients. On the contrary, the partial correlation (PARCOR) or reflection coefficients are bounded like

$$|k_m| < 1 \quad (2)$$

for $m = 1, 2, \dots, p$ when the synthesis filter is stable. Prediction coefficients can be converted to reflection coefficients and back to prediction coefficients by step-down and step-up relations, respectively (Markel and Gray, Jr. 1976). Still, the spectral sensitivity of PARCOR coefficients to quantization is different around ± 1 and around 0 (Furui 1985). Fortunately, some transformations yield more efficient parameters. The two most important sets of such parameters are θ_m , the arcsine of reflection coefficients (ASRC), for $m = 1, 2, \dots, p$ and the log area ratio (LAR) coefficients

$$o_m = \log \frac{1 - k_m}{1 + k_m} \quad (3)$$

for $m = 1, 2, \dots, p$. These parameters may be quantized uniformly.

For low sensitivity to interpolation as well, the parameters of choice are the line spectral pair (LSP) or line spectral frequency (LSF) coefficients (Itakura 1975; Furui 1985) or the immittance spectral pair (ISP) representation (Bistritz and Peller 1993). These sets of coefficients and the set of prediction coefficients are convertible to and from one another. For a stable p th-order synthesis filter, the LSFs must satisfy the relations

$$0 < w_1 < w_2 < \dots < w_{p-1} < w_p < \pi. \quad (4)$$

The ISP representation includes the immittance spectral frequencies (ISFs), which are the LSFs for the embedded p -1st-order LP component of the synthesis filter and k_p , the p th-order reflection coefficient, so that the conditions for stability of the synthesis filter include the relations

$$0 < w_{I,1} < w_{I,2} < \dots < w_{I,p-2} < w_{I,p-1} < \pi \quad (5)$$

coupled with the additional relation $|k_p| < 1$. The ISP representation incurs in lower quantization distortion in differential scalar quantization (Bistritz and Peller 1993; So and Paliwal 2007) and is used for coding the predictor coefficients in the 3GPP and ITU-T G.722.2 AMR-WB coder in split-multistage vector quantization (S-MSVQ) (Bessete et al. 2002).

For higher-quality signal reconstruction, more complex speech excitation models are used. Yet, basically the same LP analysis is done by the encoder and the same synthesis filter is used by the decoder. The first such speech coder to consider is the APC (Atal and Schroeder 1970), which features frame rate LP analysis for reestimation of the predictor coefficients, whereas the ADPCM coder uses sample rate predictor adaptation.

Code-Excited LP (CELP)

In the previous section, LP analysis techniques were presented that are quite efficient in determining the coefficients for the filter in the source-filter synthesis model in Figure 6. The configuration of the source or generator, however, has only been sketched for LPC to involve the determination of a pitch period for a periodic pulse train excitation and also a gain factor, or simply a gain factor should the excitation be random. The next step in coding these parameters is their quantization.

The analysis and coding just described for LPC is open-loop because all the parameters for the synthesis model are determined straight from the speech signal. Alternatively, a loop may be closed around a comparator between the original speech signal and a reconstructed speech signal generated by feeding the synthesis model with quantized parameter codevectors. Conceptually, in this so-called analysis-by-synthesis procedure, each quantization codevector is used to generate its corresponding reconstructed signal, and its overall reconstruction error is stored if below the current minimum value. This allows the selection of the quantization codevector causing the minimum overall error.

For CELP, the information that most clearly warrants an analysis-by-synthesis quantization is the excitation waveshape, and the "code" in the name stands for the selected waveshape quantization code. The analysis-by-synthesis search procedure through one codebook in a CELP coder is illustrated in Figure 7. Filter coefficients are quantized open-loop, and excitation gain is usually quantized in an analysis-by-synthesis loop. Original waveshapes for the codebook were drawn from an independent and identically distributed zero-mean, unit-variance Gaussian source (Schroeder and Atal 1985), segmented as 1024 codevectors containing 40 samples each. Accordingly, a 10-bit codeword was used to identify a 40-sample waveshape for a 5 ms excitation subframe.

As the search through stochastic codebooks is very computation-intensive, sparse codebooks were developed whose large amount of zero samples ease the processor. Coders such as QCELP8, IS-96 digital cellular standard (Yang, Fischer, Kang et al. 1995), and secure CELP FS-1016

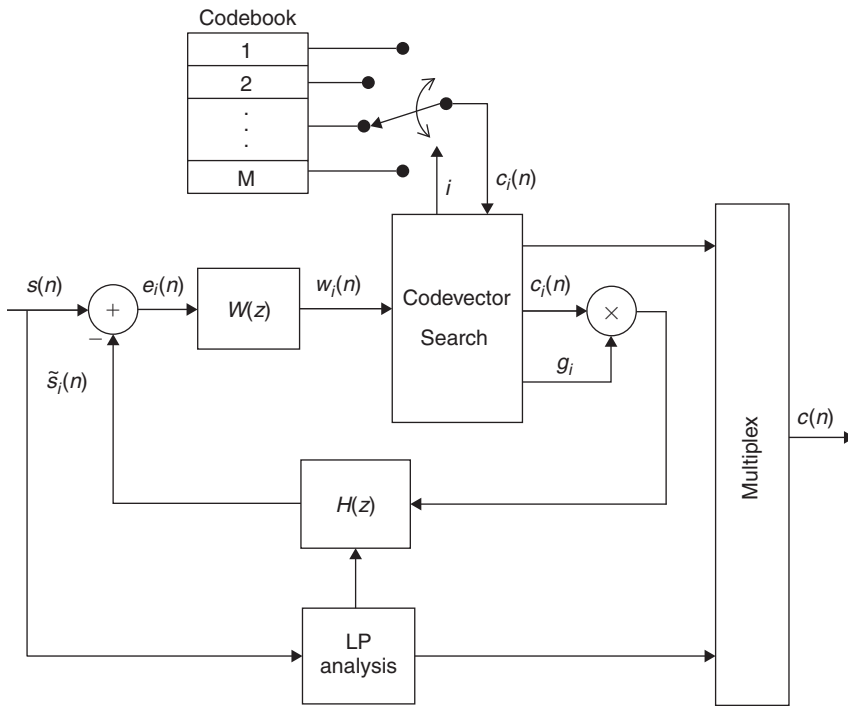

Figure 7: CELP coder encodes signal $s(n)$ into bit stream $c(n)$. Code includes analysis-by-synthesis loop driven by the reconstruction error signal $e_i(n)$

(Campbell Jr., Tremain, and Welch 1991) use sparse stochastic codebooks. Search complexity can also be reduced with focused search algorithms, which avoid testing unlikely codevectors.

The reconstruction error spectrum is shaped by the weighting filter $W(z)$ that lets less error power spread over frequency regions where the signal power density is low and allows most of the error power to appear where the signal power density is large enough to mask the error. The effect of the weighting filter upon the spectrum of the final reconstruction error signal $e_i(n)$ (see Figure 7) can be seen in Figure 8. The spectral envelope of the reconstruction error (dashed line) stays below the spectral envelope of the speech signal (solid line) when the weighting filter $W(z)$ is in the analysis-by-synthesis loop (top plot); whereas it may rise above the speech envelope (bottom plot) when $W(z)$ is not in place (bottom plot), particularly in interformant regions such as the frequency band extending from about 900 Hz to 2100 Hz. In addition, it should be noticed that the reconstruction error spectrum follows more closely the speech signal spectrum when $W(z)$ is used.

The weighting filter is adapted as a function of the synthesis filter like

$$W(z) = \frac{H(z/\gamma_2)}{H(z/\gamma_1)}, \quad (6)$$

where γ_1 and γ_2 are bandwidth expansion factors lying between 0 and 1. A usual solution is to set $\gamma_1 = 1$ and $\gamma_2 = 0.8$, but the bandwidth expansion factors for the G.729 coder are adapted according to the shape of the spectral envelope of the speech signal (Salami et al. 1998). By means of the first two LAR coefficients of the synthesis filter, the spectral shape is detected to be flat or tilted. For a flat spectrum, the factors are set to $\gamma_1 = 0.94$ and $\gamma_2 = 0.6$, while for a tilted spectrum, γ_1 is set to 0.98, and γ_2 is set to a value

Figure 8: Spectral envelopes of speech signal (solid lines on top and bottom plots) segment extracted at 0.75 s from the signal in Figure 10, reconstruction error signal at the input of the weighting filter (dashed line on top plot) in a CELP coder, and reconstruction error without weighting filter (dashed line on bottom plot)

between 0.4 and 0.7 depending on resonance strength detected by minimum LSF separation.

A strong resonance pushes γ_2 towards 0.7. Still, for WB speech, the spectral tilt is stronger so that, in order to handle it, the AMR-WB codec (Bessette et al. 2002) performs the LP analysis on the speech preemphasized by $P(z) = 1 - 0.68z^{-1}$ while using the following weighting filter

$$W(z) = \frac{1}{P(z)H(z/\gamma_1)}, \quad (7)$$

where $\gamma_1 = 0.9$.

In addition to the fixed codebook (FCB), CELP coders have a second adaptive codebook (ACB), which is an implementation of an LTP using segments of the composite excitation prior to the subframe under analysis as codevectors. The composite excitation is the linear combination of the adaptive and the fixed codevector scaled by their respective gain factors. After computing the composite excitation for the current subframe, the past excitation samples in the adaptive codebook are updated.

Usually, the lag range used in the adaptive codebook search is reduced by focusing around a delay value determined by an open-loop pitch detector. In particular, the AMR-WB codec, following the G.729 and AMR codecs, refines the lag in three stages. The second stage determines an integer value for the lag in a search around the first-stage open-loop pitch estimate, while the third stage searches for the fractional lag refinement around the optimum integer value with quarter-sample resolution at the finest time scale (Bessette et al. 2002).

For lags larger than the subframe length, the adaptive codebook is equivalent to an LTP filter, while for shorter lags, the available excitation memory is replicated. The ACB introduced previously operates out of one tap located on the past excitation memory at the pitch lag with a single gain, corresponding to a single-tap pitch prediction

$$P_h(z) = b_0 z^{-T}, \quad (8)$$

where b_0 is the ACB gain, and T is the pitch lag. Multitap ACBs may be used with taps at unit sample spacing around sample $n - T$ at one pitch lag T behind. Therefore, multitap ACBs require an odd number of gain factors, determined by crosscorrelation analysis around the pitch lag. The corresponding pitch predictor now has the form

$$P_h(z) = \sum_{i=-(p_h-1)/2}^{(p_h-1)/2} b_i z^{-(T+i)}, \quad (9)$$

where b_i for $i = -(p_h - 1)/2, \dots, (p_h - 1)/2$ are the gain factors, and p_h is the pitch prediction order. For instance, the G.723.1 coder features a five-tap ACB (ITU-T 1996b), that is, $p_h = 5$. Integer lag multitap ACBs provide additional periodicity fit over integer lag single-tap ACBs, allowing greater amplitude adjustment among harmonics, whereas fractional lag ACBs allow finer frequency resolution while providing a flat harmonic spectrum.

The noise masking effect of human hearing also applies to the harmonic component of the speech spectrum. Therefore, a harmonic weighting filter $W_h(z)$ may be defined for the open-loop pitch prediction error filter $A_{ho}(z) = 1 - P_{ho}(z)$ as

$$W_h(z) = 1 - \gamma_h P_{ho}(z), \quad (10)$$

where γ_h is a gain weighting factor constrained to be between 0 and 1 but usually lying between 0.3 and 0.4 (ITU-T 1996b; Gerson and Jasiuk 1991). The open-loop pitch predictor $P_{ho}(z)$ is usually a single-tap filter even though it may operate in a subsample time scale. For a coder with a harmonic weighting filter $W_h(z)$, filter $W(z)$ may be referred to as the formant weighting filter. Then, the resulting weighting filter will be $W(z) W_h(z)$.

The analysis-by-synthesis method used in CELP coders inherits most of its features from multipulse excitation (MPE) coders (Atal and Remde 1982). In these speech coders, the excitation for the synthesis filter consists of

$$x(n) = \sum_{k=0}^{K-1} A_k \delta(n - m_k), \quad n = 0, 1, \dots, L-1 \quad (11)$$

for a subframe of length L and K pulses whose amplitudes and locations are A_k and m_k , respectively, for $k = 0, 1, \dots, K-1$. The original proposal suggests $K = 8$ and $L = 80$ and outlines an efficient algorithm that determines pulse positions one at a time using analysis-by-synthesis, while the final pulse amplitudes are determined at the end. A more efficient search procedure came along when pulse locations were restricted to be equidistant, that is, $m_k = kS + l$, where S is the regular pulse spacing, and $l = m_0$ is the position of the first pulse or the phase of the regular pulse excitation (RPE). Therefore, regular pulse positions have to be searched only for phases $l = 0, 1, \dots, K-1$, bringing about a substantial reduction in complexity over MPE search (Kroon, Deprettere, and Sluyter 1986). The GSM (Global System for Mobile Communications) full-rate standard coder employs RPE with long-term predictor (RPE-LTP) (Hellwig et al. 1989).

Another form of deterministic sparse excitation is algebraic CELP (ACELP) excitation

$$x(n) = G \sum_{k=0}^{K-1} a_k \delta(n - m_k), \quad n = 0, 1, \dots, L-1 \quad (12)$$

where individual pulse amplitudes a_k take on values of 1 or -1 , and a common gain factor G affects all pulses. Furthermore, pulse positions are taken from tracks related by interleaved single-pulse permutations (ISPP). This means that all the positions in a subframe are distributed over K tracks so that positions on a track are equidistant, and positions on adjacent tracks are shifted. In general, just one pulse position per track will be assigned. For instance, the position grid for the G.729 coder is shown in Table 4 where one position is drawn from each of the first three tracks, and just one position is drawn from the last two tracks taken together. Therefore, 3 bits are necessary for coding each position on the first three tracks, while

Table 4: ACELP Position Grid for the G.729 40-Sample Subframe

Track	Positions							
0	0	5	10	15	20	25	30	35
1	1	6	11	16	21	26	31	36
2	2	7	12	17	22	27	32	37
3	3	8	13	18	23	28	33	38
	4	9	14	19	24	29	34	39

4 bits are needed for coding the position on the last double track. Adding on the 4 bits for coding the four pulse amplitudes, this makes for a 17-bit codebook index or a codebook holding 2^{17} waveshapes. This ACELP codebook is 128 times larger than the original stochastic CELP codebook, but its search is much more efficient due to its structured organization. Some coders assign more than one pulse position per track, such as the G.729E, EFR, and AMR coders, and the AMR-WB coder at high rates.

The gains for the FCB and ACB excitation components have to be vector quantized for low-bit-rate vocoding as a bit-rate savings measure. For instance, the G.729 coder applies VQ in the log gain domain in an analysis-by-synthesis loop while keeping the fixed and adaptive codevectors constant. Furthermore, the FCB gain is predicted by an MA (moving-average) predictor, and a correction factor is coded so that the prediction error might be decoded. This predictor removes a great deal of intersubframe gain redundancy, reducing its dynamic range and decreasing its dependence on input speech power variation (Salami et al. 1998). Also, its MA structure reduces the propagation of transmission errors.

There is more to perceptual processing than formant and harmonic weighting, which are applied to both the original and the reconstructed speech signals. Still, it has been found perceptually beneficial to include a so-called postfilter to apply on the reconstructed speech for formant, spectral tilt, and harmonic open-loop weighting. However, this postfiltering tends to degrade the codec performance under tandem connection conditions.

Finally, the lowpass nature of speech signals may cause serious numerical processing errors, mainly for fixed-point implementations. As a prevention measure, preemphasis as a preprocessing stage reduces the spectral dynamic range of the signal. This has already been mentioned in connection to WB speech preprocessing. Generally, even for NB speech, some highpass filtering is beneficial to attenuate the low-frequency power in the speech as well as to reinforce its high-frequency components. Another reason for this prefiltering is to block DC offset and attenuate additive interference such as power line induction. For instance, the G.729 reference implementation includes a second-order IIR highpass prefilter with a cutoff frequency of 140 Hz (ITU-T 1996a).

Subband and Transform Coding

Subband coding (SBC) is based on an analysis filterbank that decomposes the full-band speech signal into several

NB subband signals that may then be downsampled for independent coding by PCM, ADPCM, or analysis-by-synthesis techniques. Perceptual modeling is used for bit allocation among the subbands. In the decoder, each subband is decoded, and the full-band signal is reconstructed by the synthesis filterbank.

Practical subband filters will partially overlap causing aliasing distortion in each individual subband since critical sampling is used. Fortunately, the collective action of the analysis and synthesis filterbanks combining all the subbands after upsampling can manage to virtually cancel the aliasing distortion. The two-subband quadrature mirror filterbank (QMF) is the smallest structure capable of this cancellation effect. In fact, it is the core signal processing component in the ITU-T G.722 codec (ITU-T 1998), the first one from the ITU-T to handle WB speech, intended to be used in videoconferencing. In addition, it is one of the standard codecs in the H.323 videoconferencing protocol suite besides being a common option for VoIP systems.

The G.722 codec operates at the three bit rates of 64-, 56-, and 48 kbit/s by separating the signal into two subbands for independent ADPCM coding as shown in Figure 9a.

Conceptually, in transform coding (TC), each coefficient evolving in time may be viewed as a subband signal in SBC. In this equivalence, TC block length equals SBC subsampling factor, so constraining the impulse response of TC subband filters to be this long. Since SBC subband filters are not constrained this way, SBC includes TC as a special case. Accordingly, the design of transform coders is primarily concerned with windows and block length so that blocking artifacts constitutes an important distortion to be controlled.

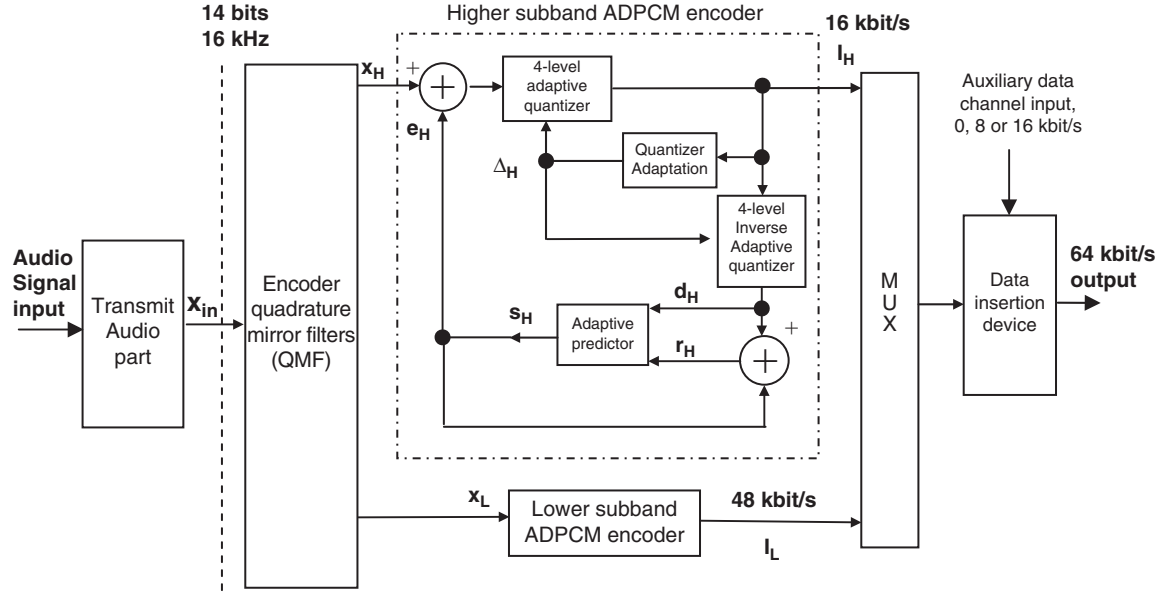

More sophisticated techniques combine subband filterbanks with transform decomposition. These techniques are employed by high-quality audio coders and by the ITU-T G.722.1 speech coder, which implements a modulated lapped transform (MLT). This codec operates at 32- and 24 kbit/s and uses a categorization procedure to determine quantizer stepsizes and parameters for regions of the MLT output as schematized in Figure 9b. The ACELP coder in Figure 9c will be explained later in the "Multirate and Variable-Rate Codecs" section in connection with the G.722.2 speech coder, also known as the AMR-WB codec. It is further noted in that section that the upper layers of the G.729.1 codec employ a TC technique.

The G.722.1 codec (ITU-T 2005c) delivers good quality music while performing not so well for speech since filterbank techniques are more suited to general audio coding (Gibson 2005).

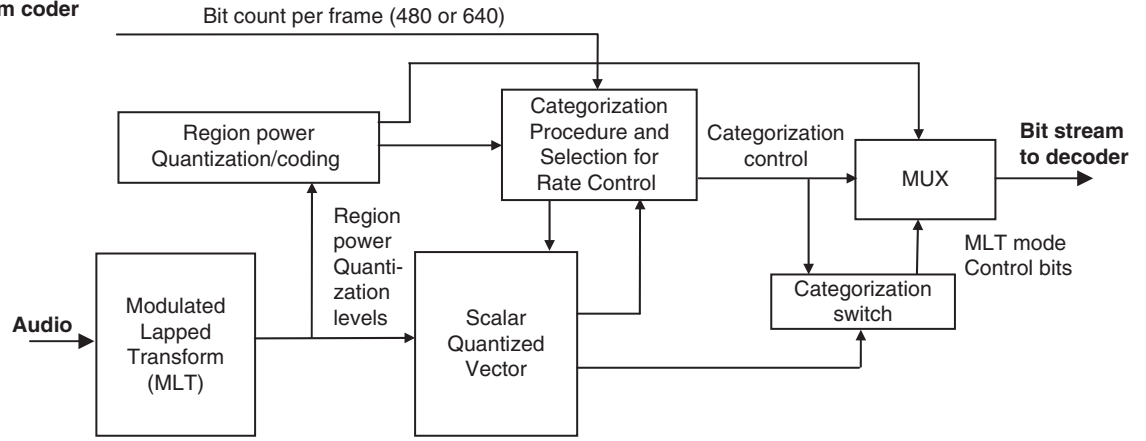

LOSS RECOVERY FOR GRACEFUL DEGRADATION

Generally, frame erasure or packet loss recovery procedures can be divided into two classes: those that use frame redundancy and those that reduce interframe dependence. Usually, speech coder recommendations such as the G.723.1 codec (ITU-T 1996b) and the AMR codec (ETSI 2004b) incorporate error concealment strategies to be applied upon

(a) ADPCM coder

(b) Transform coder

(c) ACELP coder

detection of frame erasure occurrences. These strategies apply different combinations of last good frame repetition with progressive attenuation. Their implementation may be rather sophisticated as for the AMR codec reference (ETSI 2004a), which is based on a seven-state finite state machine that counts bad frames up to six. Fixed codebook and adaptive codebook gains are adapted according to different sequences of attenuation factors depending on the value of a moving median filter. Line spectral frequencies are updated by an exponentially windowed moving average filter. Pitch lags are largely based on their most recent good values, whereas FCB indices are used as received or generated randomly if they are lost.

Even when a frame is missing when it should be played out, if it arrives while the next frame is being decoded, it may be useful in driving the inner states of the coder to where they would be in case the late frame had arrived in time (Gournay, Rousseau, and Lefebvre 2003).

The 3GPP2 VMR-WB codec conceals a frame loss after a good voiced speech frame by estimating separately the excitation frame and its envelope. Loss recovery is completed when normal frame decoding is resumed, and this may involve the construction of an artificial voiced onset that can only be done if the first good frame after the frame erasure is full-rate generic because only such frames contain all the parameters needed for recovery. But this poses no further restriction because voiced onsets are coded as full-rate generic (Jelínek et al. 2004).

Alternatively, a parameter set for a reduced resolution vocoding model may be estimated from the past good frames. In cases when no modeling is done by the encoder, the decoder itself makes a simple model by organizing previous good samples as the PLC algorithm for the G.711 coder, which is presented in the "Transmission Impairments" section.

Similar to this last strategy, a number of techniques using frame redundancy actually transmit alternate lower-resolution vocoding model parameters along the main coding stream for alternate signal reconstruction depending on the severity of the transmission impairment.

For VoIP applications, a recent development in vocoding techniques capable of graceful degradation is the Internet Low Bit Rate Codec (iLBC), which is a kind of modified CELP vocoder specified by RFC 3951 (Andersen et al. 2004) for 30 ms frames and 20 ms frames with payload rates of 13.33 kbit/s and 15.20 kbit/s, respectively. The modification breaks the main mechanism of propagation of the effects of packet losses through the adaptive codebook, which happens to be a powerful device in CELP coders. To prevent degradation from propagating across frame boundaries, the iLBC codec initializes the adaptive codebook within each frame with a start state vector that is extended forward through the end of the frame and backwards to the beginning of the frame. This process of predictive coding forward in time and then backward in time has come to be known as FB-LPC (Cable Television Laboratories, Inc. 2005).

While there is certainly a bit rate penalty to be traded in exchange for the additional robustness, it is remarkable that the iLBC coder can operate without excessive degradation for packet loss rates up to about 20 percent

(Andersen et al. 2002), while coders for mobile communications are often tested for maximum frame erasure rates of 3 percent or 5 percent (Cox and Kroon 1996).

Another development for VoIP and voice over cable and DSL applications includes BroadVoice®16, a low complexity, low delay PacketCable 1.5 mandatory 16 kbit/s NB speech codec and BroadVoice®32 WB speech codec. They implement two-stage noise feedback coding and excitation VQ with just 5 ms algorithmic delay for total complexities of 12- and 17 MIPS for BroadVoice®16 and BroadVoice®32, respectively (Chen 2007).

VOCODING STANDARDS

The most basic standard for vocoding is G.711 (ITU-T 1989) 64 kbit/s PCM, which uses waveform sampling, analog-to-digital conversion, and nonuniform amplitude coding. Its nonuniform quantizer operates at 8 bit/sample and 8000 sample/s according to a compressing-expanding law, or "companding" law for short. Actually, two companding laws are supported by the standard, namely, A-law companding that is used in Europe, South America, Africa, and Australia, and μ -law companding that is typically used in North America and Japan (Jayant and Noll 1984). The G.711 companded PCM coder was introduced in first-generation public digital telephony and its sampling frequency of 8 kHz has become standard for NB speech. However, new enhancements to vocoding such as WB speech coding are pushing the sampling frequency upwards (Cox et al. 2004).

Next in compression rate comes G.726 ADPCM at 40-, 32-, 24-, 16 kbit/s based on the use of adaptive predictor and quantizer (ITU-T 1990). It was originally established as Recommendation G.721 in 1982 by CCITT, the forerunner of ITU-T, for operation at 32 kbit/s. At this rate, it came to be used in CT2 and DECT cordless telephones. This rate accommodates 4 bit/sample of the difference signal, and both the quantizer and the predictor are backward-adapted at the sample rate from the codes delivered by the quantizer. On its upgrade to G.726, the Recommendation was extended to the three additional rates by using quantizers at 5-, 3-, and 2 bit/sample, respectively.

A further extension is Recommendation G.727, which defines an embedded coder whose quantizer levels for lower rates are exact subsets of those for the higher rates. It was intended for packet circuit multiplication equipment (PCME) (Cox 1995) as specified in Recommendation G.765 and, therefore, for packetized speech systems (Bellamy 2000) operating according to the packetized voice protocol (PVP) defined in Recommendation G.764. This protocol allows silence to be suppressed and replaced by its duration while packets are required to be sequence numbered, and nodal delay may be added to the time stamp. Additionally, G.727 classifies its bit stream into core bits, which provide for a base quality equivalent to a 16 kbit/s rate, and multiple level enhanced service bits such that each level provides for an 8 kbit/s rate enhancement. This functionality makes it possible for nodes to drop enhanced service bits in speech packets en route according to network traffic conditions.

The standardization process for a universal 16 kbit/s toll quality speech coder at ITU-T as Recommendation

G.728 was the start of a more active era in the process of defining a standard as well as in its application. First, in addition to the written recommendation, a pseudocode was provided as a reference. Further on, a bit-exact fixed-point reference implementation was also provided along with test vectors for testing compliance to the recommendation, so allowing the verification of strict compliance to the recommendation even though comparisons involving floating point implementations require the allowance of some tolerance. This new kind of “live” operational standard also motivated the provision of a floating-point reference implementation for the G.726 ADPCM coder as part of the G.191 Software Tools Library.

Since ADPCM is unable to deliver toll quality speech at 16 kbit/s, CELP was acknowledged as the vocoding technique of choice. But the algorithmic delay incurred by usual CELP coders was around 10 ms, whereas Recommendations G.711 and G.726 can be implemented with 0.125 ms of delay. So a concession was yielded by calling for a maximum one-way codec delay of 5 ms and a desirable delay below 2 ms. Actually, the winning candidate that became Recommendation G.728 has an algorithmic buffering delay of just 0.625 ms, as shown in Table 5, for a total one-way codec delay of less than 2 ms (Chen, Cox, Lin, et al. 1992; ITU-T 1992). This was achieved in a rather unusual way since this coder is backward-adapted; that is, the only code transmitted is the index to the five-sample

codevector. But, unlike usual predictor adaptation such as that used in the G.726 coder, this coder uses a 50th-order LP predictor that is estimated from reconstructed speech samples in a block basis. Also, this high-order predictor can make up for the adaptive codebook in yet another distinguishing feature from a usual CELP coder.

The following ITU-T speech coder recommendation, G.729, was meant to be applied in digital cellular communications and also in digital simultaneous voice and data (DSVD) multimedia communications where the data-bearing signal to be transmitted along with the speech signal could be related to file sharing or a fax message. In this case, low delay was not such a stringent requirement due to the inherent delay incurred by the data modems. However, toll quality remained a target, meaning quality equivalent to that of the G.726 standard.

The coder that finally met the G.729 specification (ITU-T 1996a) is the conjugate-structure algebraic CELP (CS-ACELP) coder (Salami et al. 1998). It has a deterministic sparse fixed codebook whose codevectors are composed of four signed unit pulses positioned along the forty-sample long subframe as described in the “Code-Excited LP (CELP)” section. This ACELP structure allows for efficient codebook search algorithms such as the focused search proposed for the reference coder. In this algorithm, the computation of the correlation between the codevector and a backward-filtered version of the target vector

Table 5: Operational Data for Selected Speech Coders

Coder	Algorithm	Bit Rates (kbit/s)	Frame Size + Look Ahead (ms)	Complexity (MIPS/kword ^a)
G.711 ²	Comp. PCM	64	0.125 + 0	<<1/0.001
G.726 ¹	ADPCM	40, 32, 24, 16	0.125 + 0	7.2 ^c / < 0.050 ^b

proceeds to the fourth pulse only if the joint contribution of the first three pulses exceeds a threshold. Also the computation of the energy of the reconstructed vector is terminated shortly if this intermediate condition is not met, thus saving a lot of computation.

An even lower complexity version of the G.729 coder is defined in the Annex A to the Recommendation. This G.729A coder uses an ACELP codebook search algorithm that is less complex than the focused search, as shown in Table 5, and was originally targeted to DSVD communications but is widely used for VoIP and media gateways. Also, lower average system bit rates are possible by using voice activity detection (VAD) for deciding about switching to a noise coding model for which a comfort noise generator (CNG) has to be used by the decoder and a discontinuous transmission (DTX) mode has to be understood by both the encoder and the decoder. These three features are provided by Annex B. In GSM, the DTX mechanism allows the radio transmitter to be switched off during most of the length of speech pauses, when VAD switches the codec to a lower rate noise coding mode that transmits discontinuously (Bessette et al. 2002).

Strictly speaking, DTX is a minimum source controlled rate (SCR) operation that sends comfort noise (CN) parameters during silence periods. More advanced SCR operation is performed in multimode codecs, which are discussed in the "Multirate and Variable-Rate Codecs" section. For packet voice applications such as VoIP and streaming, IETF has defined the real-time transport protocol (RTP) payload formats that include a DTX bit to support DTX operation for 3GPP AMR and AMR-WB codecs (Sjoberg, Westerlund, Lakaniemi, et al. 2002) and also for the 3GPP2 VMR-WB codec (Ahmadi 2006).

A lower-rate version at 6.4 kbit/s and a higher-rate version at 11.8 kbit/s are specified in G.729 Annex D and Annex E, respectively. Actually, G.729E is a two-mode CS-ACELP coder, where the forward-adaptive mode uses 18 bits to code the LP filter parameters for each 10 ms frame, and the backward-adaptive mode uses a 30th-order backward-adaptive synthesis filter that needs no coding bits. This latter mode is better for music, and its complexity is higher. The 18 bits freed up in the backward-adaptive mode are used to increase the excitation codes from 35 bits to 44 bits for each 5 ms subframe (ITU-T 1998). Still another interoperable codec recommendation is G.729.1, which is discussed in the "Multirate and Variable-Rate Codecs" section.

In the ITU-T collection of toll-quality speech coder recommendations, G.729 is the lowest rate one. Intensive work has been expended in defining and testing lower-rate coders, but their recommendation for toll quality has not yet been achieved. However, a lot of near toll quality coders have been deployed employing the ACELP technology used by G.729 for digital cellular applications, including all the major systems like the GSM enhanced full-rate (EFR) codec, the TIA EFR codec for the NA TDMA system, and the GSM/3GPP adaptive multirate (AMR) codec.

The GSM full-rate (FR) codec is based on RPE and LTP and operates at the speech bit rate of 13 kbit/s for a gross channel bit rate of 22.8 kbit/s (Hellwig et al. 1989). The 5.6 kbit/s half-rate (HR) GSM codec operates at the gross channel rate of 11.4 kbit/s (Gerson and Jasiuk 1993)

providing the same clean speech quality as the FR coder. The first GSM codec to provide toll quality speech was the 12.2 kbit/s ACELP enhanced full-rate (EFR) codec (Järvinen et al. 1997).

At lower rates, most of all, voiced segments have to be closely represented, and their periodicity cannot be overemphasized. One solution to this requirement is the mixed excitation linear prediction (MELP) vocoder, which meets speech quality of service for secure communications. The excitation signal has voicing determined for five frequency bands along with the first ten pitch harmonics. The degree of periodicity in the excitation may be further controlled by pulse position jitter within the period (McCree and Barnwell III 1995). The MELP codec was selected for a 2.4 kbit/s DoD Digital Voice Processing Consortium (DDVPC) standard replacement to the FS-1015 LPC-10 in 1996 (Supplee, Cohn, Collura, et al. 1997; Spanias 1994). Later the standard was extended for operation at 1.2 kbit/s.

An enhanced MELP (MELPe) coder operating at 2.4- and 1.2 kbit/s has become the NATO STANAG 4591 standard (Wang, Koishida, Cuperman, et al. 2002). The operation at 1.2 kbit/s exploits interframe redundancy by jointly quantizing the parameters for three consecutive 22.5 ms frames into what is called a superframe.

Further, there are two established implementations of sinusoidal models (McAulay and Quatieri 1995). One of them is the sinusoidal transform coding (STC) model, which does not impose harmonic relations between the oscillator frequencies, in principle, and has a voicing cutoff frequency above which the oscillator phases become random. The other one is the multiband excitation (MBE) coding model that imposes harmonic relations between the oscillator frequencies and has a voiced/unvoiced switch for each harmonic frequency band. As the Improved MBE (IMBE) codec (Kondoz 2004), a coder based on this model has been standardized for Inmarsat-M system (INMARSAT 1991).

For coders designed for voice over packet communications, refer to the "Loss Recovery for Graceful Degradation" section or the "Multirate and Variable Codecs" section, where their main features are highlighted.

Multirate and Variable-Rate Codecs

Multirate coders are capable of operating at various constant bit rates (CBRs). This enables communication in various channel traffic conditions by reducing the instantaneous bit rate when they are more stringent either because of more severe noise or when additional subscribers start sessions as usual in CDMA digital cellular communications. On the other hand, when the channel supports a higher bit rate, higher-quality speech may be delivered. This is particularly well handled by multimode coders that can control their bit rate according to the class of speech sounds being uttered. Usually, speech is classified as voiced, unvoiced, or transient voiced besides silence when voice activity is not detected.

As an example of a simple multirate coder, the G.726 codec operates at four bit rates. In addition, if the quantization levels for the lower rates are subsets of the higher rate ones, the multirate coder is said to be embedded. Simple embedded coders may be easily driven to lower rates by bit dropping as the G.727 codec discussed earlier.

As an enhanced embedded coder, the G.729-based embedded variable bit rate codec, G.729.1, is targeted at packet voice applications. Its bit rate will adapt to the network starting from a core layer at 8 kbit/s and the next one at 12 kbit/s, both for NB speech, and then stepping up in 2 kbit/s steps until a maximum rate of 32 kbit/s for WB speech for a total of 12 layers (ITU-T 2006). The coding structure consists of three algorithms that are activated in corresponding stages. The first two stages provide bandwidth scalability with an embedded CELP coding stage that operates on the lower narrow band (50-4000 Hz) for generating layer 1 and a time-domain bandwidth extension (TDBWE) parametric coding stage for the higher band (4000-7000 Hz) of the speech signal and the weighted CELP coding error signal in the lower band, comprising layer 2. The third stage is activated in layers above the second one for enhancing the full-band WB signal by applying a time-domain aliasing cancellation (TDAC), which is a predictive transform coding technique. The G.729.1 codec operates on 20-ms frames, which are actually two-frame superframes for layers 1 and 2, thereby ensuring interoperability with the base G.729 codec (Ragot et al. 2007).

Additionally, the G.729 series of recommendations includes a floating point implementation as Annex C+, integrating the base G.729 coder with its Annexes B, D, and E for provision of CS-ACELP at 6.4-, 8-, and 11.8 kbit/s with DTX functionality.

The G.723.1 ACELP/MP-MLQ codec is a dual rate speech coder for multimedia communications transmitting at 5.3- and 6.3 kbit/s. Switching between the two rates is allowed at any frame boundary. Variable rate operation may be implemented with DTX functionality, and Annex A provides VAD/CNG for higher system compression. The G.723.1 codec is included in ITU-T H.323 and H.324 Recommendations for wireline audio and videoconferencing and telephony and is also used in media gateways.

The evolution of the GSM EFR coder for NB speech and multimedia messaging services over GSM and evolved GSM (WCDMA, GPRS, and EDGE) networks is the 3GPP adaptive multirate (AMR) codec. This ACELP coder operates at 12.2 kbit/s at the same quality level as the GSM EFR codec, while its operation at 7.4 kbit/s is equivalent to the NA TDMA EFR codec (TIA/EIA 1997) and at 6.7 kbit/s, it is equivalent to the Japanese personal digital cellular (PDC) EFR (ETSI 2004b). Starting at 7.4 kbit/s, AMR provides toll quality speech while delivering near toll quality reproduction at lower rates (VoiceAge Corporation 2005). The AMR codec can operate at 8-bit rates: 4.75, 5.15, 5.9, 6.7, 7.4, 7.95, 10.2, and 12.2 kbit/s. Additionally, CN generation operates at the silence indicator (SID) rate of 1.80 kbit/s (ETSI 2004b). Bit rate switching is controlled by network conditions.

WB speech services are provided within 3GPP for GSM and the third generation WCDMA system by the Adaptive Multirate Wideband (AMR-WB) speech codec, also selected by ITU-T under Recommendation G.722.2 for WB speech coding around 16 kbit/s. It is a multirate ACELP coder operating at the nine speech coding rates of 23.85, 23.05, 19.85, 18.25, 15.85, 14.25, 12.65, 8.85, and 6.60 kbit/s. It also has a 1.75 kbit/s rate for coding CN to be used in DTX operation in GSM.

Starting from 12.65 kbit/s upward, all operating rates provide good-quality WB speech. In particular, at 23.05 kbit/s, its quality reaches that of G.722 at 64 kbit/s. Consistent with its LP base, G.722.2 performs better for speech than for music (Gibson 2005). The two lowest rates are intended to be used only under severe radio channel conditions or during network congestion (Bessette et al. 2002). Since the G.722.2 codec already includes PLC, it should be considered for VoIP applications.

The AMR-WB codec splits the full-band WB speech signal into two bands. The lower band from 50 to 6400 Hz is most perceptually important. Only the 23.85 kbit/s mode encodes the higher band gain as shown in Figure 9c.

A multimode codec is capable of operating at an average bit rate (ABR) that characterizes each mode of operation. The ABR is the result of a source-driven mixture of CBRs. The collection of CBRs is referred to as a rate set. In CDMA systems, the component CBRs are called full rate (FR), half rate (HF), quarter rate (QR), and eighth rate (ER). A mode establishes a quality of service (QoS) for speech reproduction, and rate selection depends on characteristics of the speech signal within bounds set by the established quality level.

Two rate sets are supported in CDMA systems. In Rate Set II, a variable rate codec may operate at the source coding bit rates of 13.3 (FR), 6.2 (HR), 2.7 (QR), and 1.0 (ER) kbit/s. The 3GPP2 variable-rate multimode wideband (VMR-WB) speech codec operates in four modes (Jelínek et al. 2004):

- *Premium mode*: ABR specified to be equivalent to that of QCELP13 (IS-733), was designed to be equivalent to AMR-WB at 14.85 kbit/s.
- *Standard mode*: ABR specified to be the average of those of QCELP13 and EVRC (IS-127), was designed to be equivalent to AMR-WB at 12.65 kbit/s.
- *Economy mode*: ABR specified to be equivalent to that of EVRC, was designed to be equivalent to AMR-WB at 8.85 kbit/s.
- *Interoperable FR*: Still, VMR-WB may operate at a fourth mode for compatibility at 12.65 kbit/s with systems using the AMR-WB codec. This mode includes 13 extra bits in the frame to fit the 13.3 kbit/s full rate.

For packet voice applications, two payloads for assembling packets for the VMR-WB codec bit stream are specified in IETF RFC 4348 (Ahmadi 2006; Ahmadi and Jelínek 2006). In particular, the header-free payload format provides for rate efficiency and low latency in VoIP applications although it is not compatible with AMR-WB RTP payload.

Rate determination for the VMR-WB codec is done in stages (Jelínek et al. 2004). At first, VAD classifies speech and silence. Active speech frames are classified as unvoiced and voiced. Voiced frames are further classified for stability by means of a signal modification procedure. If declared stable voiced, the frame is handed to the Voiced HR encoder. Finally, if the frame is not classified as stable voiced, it is deemed likely to contain an onset or a voiced

transition and set to be encoded as an FR type. But, frame energy may override this classification if it does not reach a given threshold. Then, the frame is encoded as Generic HR.

The signal modification procedure used in the VMR-WB codec to classify voiced frames (Tammi, Jelínek, and Ruoppila 2005) incorporates a very important technique called generalized analysis-by-synthesis (Bastiaan Kleijn, Ramachandran, and Kroon 1992) or relaxed CELP (RCELP). It involves the modification of the original signal to a perceptually equivalent version that is better suited to the encoding algorithm. It often consists of a variable time warping that reduces the encoding rate of the ACB in a CELP coder.

Previously, two other variable-rate codec standards have incorporated the RCELP technique. They operate at Rate Set I, including the source coding bit rates of 8.55 (FR), 4.0 (HR), 2.0 (QR), and 0.8 kbit/s (ER). The 3GPP2 Selectable Mode Vocoder (SMV) coding technique is dubbed extended CELP (eX-CELP) and it operates in modes 0, 1, and 2 at ABRs of 7.3, 5.1, and 4.1 kbit/s, respectively (Gao et al. 2001). In mode 1, the SMV was designed to perform similar to IS-127. The TIA IS-127 Enhanced Variable-Rate Coder (EVRC) (TIA/EIA 1996) is an RCELP/ACELP codec whose rate determination algorithm lacks flexibility since it does not use the quarter rate at all and hardly uses the half rate (Gao et al. 2001).

At the same quality level, the EVRC was designed to operate at a lower bit rate than TIA IS-733 codec, also known as QCELP13 since it operates at Rate Set II and employs the Qualcomm CELP (QCELP) coding technique.

A codec functionality provided by enhanced embedded coding is scalability. A scalable codec issues several bit streams, referred to as a core bit stream and enhancement bit streams. The core bit stream provides a complete description for a minimum resolution signal reconstruction. Enhancement bit streams provide finer reconstruction if received by the decoder.

Scalable coders may have SNR or bit rate scalability and also bandwidth scalability. In bandwidth scalable coding, the enhancement bit streams provide parameters for reconstructing extended frequency bands. An example consists of a core bit stream for NB coding and an enhancement bit stream such that the combination of both bit streams will provide for WB coding as mentioned previously in connection with the G.729.1 codec.

Another example of scalable coding is the MPEG-4 natural audio coding toolbox (Brandenburg, Kunz, and Sugiyama 2000). For lower bit rates of 2 kbit/s and 4 kbit/s, it provides for NB speech the harmonic vector excitation coder (HVXC), which performs preliminary pitch estimation and LP analysis of the speech signal whose residual signal is Fourier transformed to the frequency domain where detailed pitch analysis and envelope VQ is performed for voiced speech. For unvoiced speech, the excitation is searched from a codebook in the time domain. The HVXC coder is the association of the LSP VQ tool and the harmonic VQ tool. Higher bit rates and 3.85 kbit/s are handled by the CELP coder, which may be selected from a set of 28 bit rates for NB speech up to 12.2 kbit/s and 30 bit rates from 10.9 kbit/s to 23.8 kbit/s for WB speech. The CELP coder consists of the LSP VQ tool coupled to

the MPE tool or the RPE tool. The latter is used just for WB speech for lower complexity.

Targeted at packet voice communications, Speex is an open-source multirate embedded speech coder. Additionally, it features source-controlled variable rate coding, VAD and DTX operation, besides variable search complexity. The LSF coefficients are the only parameters coded at the 20 ms frame period by means of nonpredictive VQ for packet loss resilience. Speex can code NB speech at bit rates from 2.15 kbit/s to 24.6 kbit/s. For WB speech coding, a QMF splits the signal into two subbands, which are CELP coded using a subband CELP (SB-CELP) technique where the lower band is coded by the NB CELP encoder, while the higher-band CELP encoder neglects pitch period information. In the latter case, pitch is not used because the periodicity in the higher band is said to be severely affected by the aliasing caused by the filterbank. Speex rates for WB speech range from 3.95 kbit/s to 42.2 kbit/s (Valin and Montgomery 2006).

Multiple description coding is another diversity-based communication strategy. Multiple description coders send bit streams with independent complete and complementary descriptions of the signal so that with any number of arriving descriptions, the decoder will reconstruct the signal at a partial resolution level.

TRENDS IN LOW-BIT-RATE CODING

In general, lower bit rate vocoders are bound to track the speech signal in a time-frequency domain where they should identify a pattern change in either the time or the frequency domain or even in both. We can loosely identify such changes with speech events that could lead to the ultimate low-bit-rate coder if they could be reliably identified and coded.

We can use the spectrogram as a guide; the spectrogram is a powerful instrumental representation of speech signals that has aided phonetic research ever since its invention in the 1940s (Koenig, Dunn, and Lacey 1946). The two usual operating modes to take a spectrogram are wideband and narrowband and both are exemplified in Figure 10. A wideband spectrogram displays the formant structure in its pattern of frequency bands, whereas the periodicity shows in the pattern of time striations. On the other hand, a narrowband spectrogram displays the periodicity as a set of thin frequency tracks. In other words, a wideband spectrogram has larger time resolution, and a narrowband spectrogram has larger frequency resolution.

From a vocoding standpoint, there are two rather different models of harmonic coders that are roughly analogous to the two modes of taking spectrograms. A sinusoidal model is a set of narrowband oscillators that can be driven by a kind of narrowband spectrographic analysis. On the other hand, a WI coder extracts pitch-length cycles during voiced speech and arbitrary length waveform segments during unvoiced speech. All extracted cycles and segments are stretched to a common length and laid out sideways to the time evolution axis in a two-dimensional arrangement (Bastiaan Kleijn and Haagen 1995). Their Fourier-series coefficients or other transform coefficients are usually employed instead of the cycles themselves.

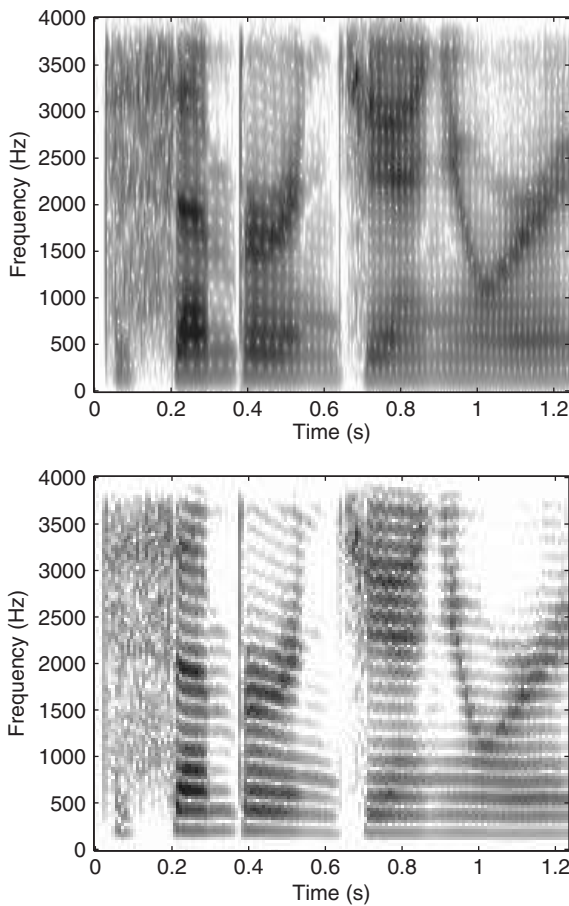

Figure 10: Spectrograms in two resolutions, wideband spectrogram (top) and narrowband spectrogram (bottom), for the truncated phrase “December and January...”, uttered by a female speaker

The characteristic waveform (CW) surface so obtained is lowpass filtered along the evolution axis to uncover the slowly evolving waveforms (SEWs), which also define the rapidly evolving waveforms (REWs) when subtracted from the CWs. Both can be efficiently coded since SEWs can be coarsely interpolated in time but require fine resolution in frequency, whereas REWs require almost no frequency resolution but have to be interpolated rather frequently in time.

Speech coders based on codebooks of sequences of speech subunits with properly defined distortion measures will also play an important role in advancing the toll quality frontier into the bit-rate range below 1 kbit/s (Arjona Ramírez and Minami 2003). Codebooks of speech subunits are used by concatenative synthesizers and may be used in a speech coding structure under some constraints for prosody modification (Lee and Cox 2001).

The idea of speech events may be implemented in different ways. Temporal decomposition (TD) is based on the notion that parameter tracks could be composed with localized interpolation functions, each located where an event occurs and fading when going away from it. Essentially, the parameter values at event locations only are coded along with a coarse representation of the interpolation

functions. Events then behave as targets and interpolation functions are the weights that allow the reconstruction of the parameter tracks. This decomposition was proposed by Bishnu Atal to be used with LAR tracks (1983). It has been applied to LSF tracks, which are the most popular LP representation in speech coding (Nguyen and Akagi 2002) and has also been proposed for excitation parameters as well (Nandasena and Akagi 1998).

Temporal decomposition may be used to find a representation of speech parameters for a speech recognizer to chop the signal in segments. The recognizer may be trained automatically in the case of a segment vocoder (Černocký, Baudoin, and Chollet 1998). Speech segments for segment vocoders may be represented by their waveform and only be parameterized for time scale and pitch scale modifications (Roucos and Wilgus 1985). Coding rates around 300 bit/s may be obtained by segment vocoding.

If the speech recognizer, usually based on Hidden Markov Models (HMMs), in a segment vocoder is trained on phonetic units and concatenated phonetic units, then a phonetic vocoder is obtained. These vocoders can operate at around 100 bit/s (Tokuda, Masuko, Hiroi, et al. 1998).

The evolution of these techniques to higher speech quality is bound to increase the range of communication services supported by speech coding. But, these source coding techniques for low-rate speech coding also find application in enhancements to normal NB communication services such as bandwidth extension (BWE) to provide greater phoneme identification and speaker recognition (Jax and Vary 2006). Of course, BWE depends on some additional information about the signal that may be added by a system previously trained with true WB speech and its NB version.

True WB speech is better if available through the communications network even though BWE is still useful in connecting to NB terminals. As discussed before, the development of the AMR codec ushered in a great evolution in WB speech coding, continued with the AMR-WB and VMR-WB codecs.

Wider bandwidths up more than 19 kHz are supported by the 3GPP Extended AMR-WB (AMR-WB+) codec specified in 2004 for high-quality audio on mobile services (Salami et al. 2006). It is based on a hybrid ACELP and transform coded excitation (TCX) technology operating at several bit rates between 6 and 48 kbit/s. The use of ACELP allows good performance for speech signals at the lower rates.

More recently, a super-wideband (14 kHz bandwidth and 32 kHz sampling rate, refer to Table 1) codec has been specified as Annex C to the ITU-T G.722.1 Recommendation (ITU-T 2005c). It is a low complexity MLT codec operating at 24-, 32-, and 48 kbit/s with 20 ms frames, intended for videoconferencing, teleconferencing, and Internet streaming applications. A fixed-point reference source code and a series of test vectors is provided along with the Recommendation.

To cope with the increasing trend toward widespread multimedia applications, codec designers will have to wield the potential of different strategies such as scalable and multiple description coding. This will take a lot of hard work in research and development of vocoding technologies.

CONCLUSION

The selection of a speech codec involves many considerations, precluding a single solution. Besides the basic operational dimensions of bit rate, distortion or quality, complexity and delay, system constraints and connections with different networks have to be given due attention.

In some cases, the availability of a suite of codecs using the same technology or complying to some standard for interoperability may provide a wide-ranging solution. This happens to be the case for the ITU-T G.726/G.727 ADPCM coders; the ITU-T G.729 CS-ACELP codec and its Annexes, also including Recommendation G.729.1; and the ETSI/3GPP AMR codecs, including multiple ACELP coding rates.

However, other constraints such as low complexity, low power, and low delay may restrict the offer of speech codecs available for the task and call for new developments.

New challenges in multimedia communications will require the concerted application of multiple technologies. These efforts will eventually lead to new technologies drawing from evolving research in source coding and communications. In turn, research efforts are expected to increase.

GLOSSARY

3GPP: The 3rd Generation Partnership Project is a collaboration agreement that was established in December 1998. It brings together a number of telecommunication standards bodies, including ETSI.

ABR: Average bit rate for a speech quality level is the average data rate that the codec will keep by switching between coding algorithms or layers for different types of speech sounds.

ACELP: Algebraic CELP refers to a CELP codec whose fixed codevectors are a sum of a few positive or negative unit pulses.

ADM: Adaptive delta modulation is a differential speech coding technique that uses a two-level backward-adaptive quantizer and a fixed predictor. The stepsize is adapted, and the one-bit codeword is interpreted as the algebraic sign that affects the current stepsize.

ADPCM: Adaptive differential PCM is a speech coder that uses a backward-adaptive PCM quantizer to code the difference signal sample that results when the predicted sample is subtracted from the speech sample. In turn, the predicted sample is generated by the backward-adaptive predictor from previous quantized samples. More specifically, ADPCM may refer to ITU-T Recommendation G.726/G.727.

AMR: ETSI GSM/3GPP adaptive multirate codec consists of integrated ACELP codecs that operate at eight bit rates from 12.2 kbit/s to 4.75 kbit/s. The highest rate codec is the same as GSM EFR (enhanced full-rate) codec.

Analysis-by-Synthesis: In a CELP encoder involves the use of an exact replica of the decoder for generating the reconstructed speech vector in the process of excitation codevector search. This procedure ensures that the encoder will track the decoder in the absence of transmission errors.

ANSI: The American National Standards Institute is a private, nonprofit organization that administers and coordinates the U.S. voluntary standardization and conformity assessment system.

APC: Adaptive predictive coding is a technique used in a type of adaptive differential PCM codecs whose quantizer and predictor are forward-adaptive; that is, their parameters are adapted based on a block of original speech signal samples at the frame rate.

Bit Rate: is the rate of serialized coder output. It may be a time rate measured in bit/s or referred to the signal sampling when measured in bit/sample.

Bit Stream: A sequence of bits generated by the ordered serialization and concatenation of the codewords for all encoder parameters.

CBR: Constant bit rate refers to the data rate for a codec based on fixed-length framing.

CCITT: Comité Consultatif International Téléphonique et Télégraphique, international organization that set communications standards until 1993. Now known as ITU.

CELP: Code-excited linear prediction is a speech coding technique that uses a codebook of codevectors to be input to a synthesis filter capable of producing a near match to a block of speech signal samples. The selection of codevector is carried out in an analysis-by-synthesis loop. CELP codecs are usually distinguished by their codebook structures and their codevector search algorithms.

Channel: The medium for communication between encoder and decoder. It may be modeled as a two-port component that adds noise and delays to the data-bearing signal, besides causing incidental phase distortion. Alternatively, the channel may be described by its capacity, or maximum bit rate, and the statistical bit error rates observed at the decoder. It is interesting to note that a store-and-forward system may also be modeled as a channel whose longer delay is not usually an application issue.

EIA: Electronic Industries Alliance is a national trade organization that includes the full spectrum of U.S. manufacturers. The Alliance is a partnership of electronic and high-tech associations and companies.

ETSI: European Telecommunications Standards Institute.

GSM: Global System for Mobile Communications.

G.XXX: It stands for all ITU-T recommendations with prefix G. See <http://www.itu.int/publications/publications.aspx?lang=en&parent=T-L&selection=2§or=2>. ITU-T Recommendations for "Transmission systems and media, digital systems and networks."

H.XXX: It stands for all ITU-T recommendations with prefix H. See <http://www.itu.int/publications/publications.aspx?lang=en&parent=T-L&selection=2§or=2>. ITU-T Recommendations for "Audiovisual and multimedia systems."

ITU-T: Telecommunication Standardization Sector of the International Telecommunication Union (ITU), which is an international organization within the United Nations System.

LP: Linear prediction is the process that generates a match to a speech signal sample by a linear

combination of past samples. The weights in this combination are adjusted to make a block of predicted samples match the original block of samples in the mean-square sense, and this estimation is what LP often stands for.

LPC: Linear predictive coding is a parametric vocoding technique that uses a synthesis filter determined by LP analysis, and its excitation is either a periodic pulse train whose repetition rate and amplitude may be adjusted or a pseudorandom sequence whose power may be adjusted. Some LPC vocoders may combine both excitation sources.

NB: Narrowband speech is a signal in the frequency band ranging from 300 Hz to 3.4 kHz sampled at 8.0 kHz.

PCM: Pulse code modulation originally refers to the transmission of a bit stream by a sequence of pulses where each one of them is associated to a bit. In source coding, PCM stands for the quantization process that generates the codewords in the bit stream from the speech signal samples.

TIA: Telecommunications Industry Association represents the communications sector of EIA.

WB: Wideband speech is a signal in the frequency band ranging from 50 Hz to 7.0 kHz sampled at 16.0 kHz.

INTRODUCTION

Recent years have seen a growing interest in the transmission of voice using packet-based protocols. Voice over Internet protocol (VoIP) is a rapidly growing technology that enables the transport of voice over data networks such as the public Internet. VoIP has been discussed since the early 1970s (Varshney et al. 2002), when the idea and technology were developed. At that time, however, VoIP did not find wide acceptance and deployment among users or telecommunication providers. This was mainly due to the lack of IP infrastructure and the fact that circuit-switched calling was still a much more reliable alternative, especially with regard to the poor quality of early VoIP calls. However, following the rapid growth of the Internet in the mid-1990s, and large investments in the IP networking infrastructure by businesses, vendors, and carriers, VoIP increasingly became a viable alternative to sending voice over public switched telephone networks (PSTNs).

The basic idea behind VoIP involves the transmission of voice as data packets using IP. The user's voice is converted from an analog form into a digital signal, compressed (or uncompressed), and is then broken down into a series of packets (packetization). These packets are routed through public or private IP networks—from one user to another—and are reassembled and decoded (if compressed) at the receiving end, as shown in Figure 1.

VOIP BACKGROUND

VoIP Growth

VoIP was first used as a simple way to provide point-to-point voice transport between two IP hosts, primarily to replace expensive international phone calls. However, the growing interest in providing integrated voice, data, and video services has expanded its scope; IP telephony now encompasses a range of services. These include traditional conferencing, call-control supplementary services,

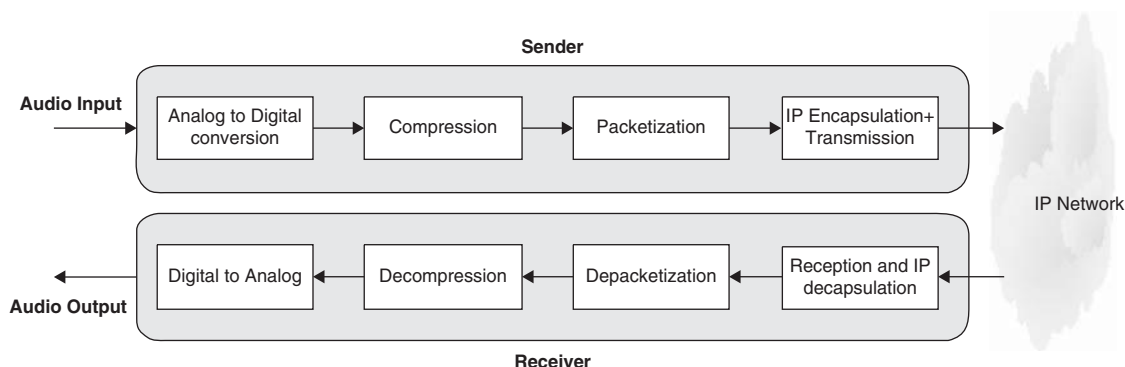

Figure 1: Basic operations in a VoIP system

multimedia transport, and mobility, as well as new services that integrate Web, e-mail, presence, and instant messaging applications with telephony. Furthermore, it is generally accepted that IP telephony and traditional circuit-switched telephony will coexist for quite some time, requiring gateways (nodes that interconnect data networks such as the Internet and wide area networks [WANs] with the plain old telephone system [POTS] networks) between the two worlds.

Voice has been transmitted over PSTNs for almost over a century; in the United States, the long-distance voice market has grown to about \$100 billion a year in business and residential demand. The desire of businesses and consumers to reduce this cost, along with substantial investments over recent decades in IP-based networks—both public and private—has generated substantial interests in delivering VoIPs (Varshney et al. 2002). Several recent industry surveys and projections estimate that VoIP could account for over 10 percent of all voice calls in the United States by 2006. In fact, VoIP is likely to be used first in places with significant IP infrastructure or where cost savings are significant. One example would be a company with multiple sites worldwide connected through a private or public IP network.

The Asia Pacific region is also expected to be one of the leading markets for VoIP services. Asia registered a volume of about 175.2 billion minutes of VoIP calls in 2004, and the total VoIP calling minutes are expected to reach 484.2 billion by 2009. During the same period, VoIP service revenue is expected to rise from \$5.5 billion to \$10.8 billion (Asia Networking/Telecom 2006). The rapid proliferation of VoIP services in the Asia Pacific region can be attributed to the existence, until recently, of monopolies in the telecommunications sector in most markets. In most cases, prices have been set considerably higher than in other regions. As a result of high price sensitivity, customers from the Asia Pacific region would be more willing to switch to cheaper VoIP services.

BENEFITS OF VOIP

Several factors influence the adoption of VoIP technology (Varshney et al. 2002). Some of the major ones include:

- **Cost savings:** The cost of a packet-switched network for VoIP could be as little as half that of a traditional circuit-switched network (e.g., the PSTN) for voice transmission. This expected cost savings is the result of a more efficient use of bandwidth requiring fewer long-distance trunks between switches. The price of a VoIP phone line is a fraction of the cost of a traditional telephone line; long-distance calls are much less expensive if they are made via a VoIP provider, and applicable taxes are far lower with VoIP phone service than with a traditional phone service. For example, some phone service providers offer a phone line for around \$9 per month and will charge between one and three cents per minute per call, depending on the provider. Most VoIP phone providers offer a bundled service that includes unlimited incoming calls and unlimited long distance

calls to anyone in the United States or Canada for one small fee. VoIP also enables low taxes. Governments have thus far taken a hands-off approach to VoIP service providers: because calls are carried over the Internet, governments have not heavily taxed VoIP phone services.

At present, the only tax users can expect to see on a VoIP phone service provider's bill is a federal excise tax, which accounts for only 3 percent of the cost of the service (for example, if a user chooses a \$19.95 unlimited calling plan, the federal excise tax would equal 3 percent of \$19.95, or sixty cents). This cost is much lower than taxes on a local telephone bill, resulting in significant savings. Moreover, most VoIP phone providers include features such as free voicemail, call forwarding, caller ID, call waiting, call waiting ID, three-way calling, and speed dialing for a minimal monthly fee, compared to traditional phone companies that have significantly higher charges for similar services.

- **Improved network utilization:** The traditional circuit-switched networks have to dedicate a full duplex 64 kbits/s channel for the duration of a single call, whereas, with VoIP networks, the bandwidth is used only when something has to be transmitted. More efficient use of bandwidth enables more calls to be carried over a single link without requiring the carrier to install new lines or further augment network capacity.
- **Opportunities for value-added services:** VoIP offers other features, including caller ID and call forwarding, that can be added to VoIP networks at minimal extra costs.
- **Integrated infrastructure:** VoIP allows Internet access and voice traffic simultaneously over a single phone line, potentially eliminating the need for two phone lines in a home (one for data and one for voice).
- **Progressive deployment** (Varshney et al. 2002): IP telephony is an additive to today's communications networks because it can be easily integrated with existing PSTN infrastructure and networks. One area of concern with VoIP that remains is connectivity with the 911 service (i.e., emergency services).

RECENT TRENDS IN VOIP

There are expected to be approximately 19.2 million residential VoIP lines in use by the end of 2007, as shown in Figure 2 (eMarketer 2005). The low cost, efficiency, and flexible nature of VoIP are leading to its increasing

Figure 2: VoIP access lines in the United States (eMarketer 2005)

Figure 3: Growth of VoIP products (eMarketer 2005)

acceptance in the marketplace. In fact, as the telecom industry regains momentum from its 2002 decline, and large service providers complete depreciation of their legacy investments, more bundled offerings are emerging on the market—many of which integrate voice and data capabilities. Moreover, as Figure 3 illustrates, the growth of VoIP products over the five-year forecast is strongly skewed toward the later years.

HARDWARE-BASED RESIDENTIAL VOIP SERVICES IN THE UNITED STATES

A wide variety of VoIP products and services are available on the market today. Some of these different types of VoIP products are described as follows.

Gateways: Allow analog and digital voice/fax communications over IP networks or the Internet. They can be used for origination and/or termination. They are the backbone of most VoIP networks and service providers, and they support H.323 and/or SIP.

Gatekeepers: Allow centralized control of gateway administration and call routing. They also allow load balancing and a single IP address for multiple gateways.

Advanced gateway options: For VoIP applications requiring advanced functionality and higher performance, these specialized products provide features not normally found in standard gateways or gatekeepers.

Digital phone sets to VoIP: VoIP gateways that allow most popular private branch exchange (PBX) digital phone sets to retain their full functionality across an IP network or the Internet. Popular PBXs include Nortel, Avaya, Definity, Alcatel, Panasonic, Toshiba, and more.

Cellular to VoIP: In many countries, cellular global system for mobile (GSM) telecommunications, code division multiple access (CDMA), or time division multiple access (TDMA) may be the only cost-effective choices for voice communications. These systems allow VoIP transmissions to terminate on standard GSM and/or CDMA/TDMA networks.

VoIP billing: Allows service providers and organizations to extract data about voice and fax calls from VoIP

gateways or gatekeepers. This allows full control of VoIP networks that support services such as prepaid, post-paid, or wholesale.

Gateway channel banks: Many digital VoIP gateways with E1, T1, or primary rate interface (PRI) voice ports may require access to analog PSTN phone lines. With these devices we can convert E1, T1, or PRI voice interfaces from most gateways to either foreign exchange subscriber (FXS) or foreign exchange office (FXO) interfaces (the two most common interfaces found in analog telephony environments).

Table 1 provides a snapshot of prices and features for some of the major hardware-based residential VoIP services in the United States. New VoIP services are continuously emerging on the market, and prices and features change rapidly. Many more providers, especially the established cable and phone companies, are entering the VoIP market (Tripos Corporation 2005).

A COMPARISON OF VOIP AND VOICE OVER PUBLIC SWITCHED TELEPHONE NETWORK

The PSTN has served the needs of businesses and consumers worldwide for more than 100 years and has gone through major technological advances, including resilient and robust long-distance networks based on technologies such as synchronous optical network (SONET), intelligent networking, Signaling System No. 7 (SS7)-based signaling, and a high degree of redundancy in telephone switches. All of these advanced features and components have considerably increased the reliability of PSTN, which is today operational 99.999% of the time (Wright 2001) and offers low latency rates and very high quality during voice transmissions.

IP-based networks are now ubiquitous and are being used to provide integrated voice-data communications. As a result, conventional PSTN carriers realize they have to respond to this competitive capability (handling of integrated voice-data transmissions) of IP technology. For example, Telcordia (formally Bellcore) has developed a Voice over Packet (VoP) architecture and has initiated an

Table 1: VoIP Service Providers in the United States

VoIP Service Provider	Cost per Month	Features
AT&T CallVantage	\$30	Voicemail to e-mail, speed dialing, call logs, Do Not Disturb, a flexible call-forwarding feature called "Locate Me," and a conferencing system for up to nine users. AT&T also offers number portability and 911 service.
BroadVoice	\$20	Selective call forward and blocking, lets customers choose their own session initiation protocol (SIP)-compatible devices.
Broadvox Direct	\$20	Do Not Disturb, contact management, Find Me, and Follow Me.
EarthLink Unlimited Voice	\$30	911 emergency service, 411 directory assistance, multiple lines and virtual numbers, personalized voicemail, and a \$10/month fax line. There is also a bandwidth-saver feature for those with limited upstream broadband speeds, letting them adjust their voice quality based on available bandwidth.
Net2Phone	\$35	Toll-free plans, flexible pay-as-you-go plans, and add-on options offering minutes to particular international regions and countries. Other features include call blocking and the ability to make local and long-distance calls.
Packet8	\$20	Voicemail to email; 911 service for \$3 a month; and a videophone plan that provides unlimited phone and videoconferencing calling for \$30 a month plus a \$30 activation fee.
Time Warner Cable Digital Phone	\$40	911 service, voicemail, and the ability to rewire all existing phones through regular phone jacks to the cable modem router.
Verizon VoiceWing	\$35	911 service, address books with click-to-dial settings, enhanced call forwarding, and speed dialing.
VoiceGlo	\$30	Voicemail and customized call following.
VoicePulse	\$35	Call blocking, Do Not Disturb, multi-ring, contact management, and a sophisticated customized call following feature. Directory assistance is available at extra cost.
Vonage	\$25	911 access, voicemail with access available via e-mail or the Web, number portability, 411 directory assistance, additional voice and fax lines, and a PC-based soft-phone version of Vonage.

industry-wide effort to develop generic requirement documents; the documents are expected to allow local and interexchange carriers, vendors, and other stakeholders to address interoperability issues associated with networks, services, protocols, and equipment. These initiatives recognize that distinct networks cannot cost-effectively offer bundled services, and there is therefore a strong need to identify a migration path for PSTN carriers to preserve their investments in circuit-switched technology and services. This migration path is supposed to allow PSTN carriers to modify and add only some components to existing networks to offer multiple services, including VoIP (Varshney et al. 2002). As mentioned previously, VoIP offers end users a great deal of features and cost savings compared to the traditional PSTN. Table 2 presents a comparison of the main features of Voice over PSTN and Voice over IP technologies.

VoIP IMPLEMENTATION CONFIGURATIONS

The overall technology requirements of an IP telephony solution can be split into four categories: signaling,

encoding, transport, and gateway control. The purpose of the signaling protocol is to create and manage connections between endpoints, as well as to create and manage calls. Next, when the conversation starts, the analog signal produced by the microphone from the human voice needs to be encoded in a digital format suitable for transmission across an IP network. The IP network then transports the real-time voice content across the available media and needs to maintain an acceptable level of voice quality. In some cases, the IP telephony system may also need a gateway (also known as a VoIP gateway) to convert from the digital format to another format—either for interoperability with a different IP-based multimedia scheme or because the call needs to be placed on PSTN.

VoIP Hardware Configurations

PC-to-PC Configuration

The PC-to-PC configuration is the simplest VoIP design because the conversion from voice to data and back is performed on a PC using a sound card and the appropriate software. As Figure 4 shows, calls can only be made within the data network (in this case, within the Internet).

Table 2: A Comparison of Voice over PSTN and Voice over IP Features

Feature	Voice over PSTN	Voice over IP
Switching	Circuit switched (end-to-end dedicated circuit set up by circuit switches)	Packet switched (statistical multiplexing of several connections over links)
Latency	Less than 100 milliseconds	200–700 milliseconds (depending on the traffic on the IP network)
Bandwidth	Dedicated	Dynamically allocated
Equipment	Dumb terminal (cheap); intelligence in the network	Integrated, smart, programmable terminal (expensive); intelligence not in the network
Quality of Service (QoS)	High (extremely low loss)	Low and variable; QoS depends on the amount of traffic, packet loss, and delay experienced
Network Availability	99.99% uptime	Level of reliability is unknown
Electrical Power Failure	Not a problem; powered by a separate source from the telephone company	May have problems with equipment being down
Security	High level of security because one line is dedicated to one call	Possible eavesdropping at routers
Standards/ Status	Mature (simplified internetworking between equipment of different vendors)	Emerging; possible problems in internetworking
Carrier Lines	Dedicated lines required from the telecommunication companies	All voice channels can be transmitted over one Internet connection
Bandwidth	Each analogue telephone line uses 64 kbits/s in each direction	Using compression, VoIP can use as little as ~10 kbits/s in each direction; further bandwidth can be saved by using silence suppression (not transmitting when the person is not speaking)
Advanced Features (e.g., call waiting, caller ID, conferencing, on hold, etc.)	Often available at an extra cost	Generally available for free
Remote Private Automatic Branch Exchange (PABX) Extensions for Teleworkers and Branch Offices	Very costly and require dedicated lines for each remote extension	Remote extensions are a standard feature
Expansion and Upgrade	Complex: can require significant hardware additions, provisioning of new lines, etc.	Often just requires more Internet bandwidth and software upgrades
Choice of Companies to Terminate Calls	Each line is provisioned by a single telecommunication company, meaning there is very limited least-cost routing	Hundreds of VoIP providers to choose from to terminate calls
Typical Business Line Rental	\$40 per month	\$11 per month
Free Calls	None	To other VoIP users of the same gateway

Source: Varshney et al. (2002)

Such a configuration requires that both users be on-line during a conversation. This implies that users have to plan their calls in advance, or one of them must call the other using a standard phone (PSTN phone) in advance. Only then can the users start a VoIP conversation. This makes a call very time consuming, especially when

both users are connected to the Internet via a modem connection.

PC-to-POTS Configuration

The next step in the VoIP evolution was to exploit a VoIP gateway. A gateway is a node that interconnects data

Figure 4: PC-to-PC VoIP scenario

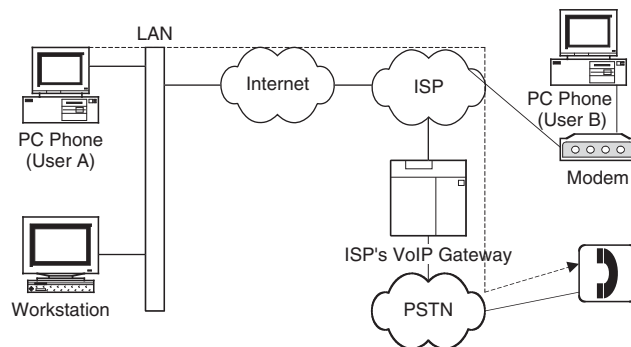

Figure 5: PC-to-POTS VoIP scenario

Figure 6: Phone to phone via IP

networks (e.g., local area network [LAN], Internet, WAN) and POTS networks. Some Internet service providers (ISPs) offered new services for IP telephony via gateways. Now users could call the other party from their PC to POTS telephones.

As shown in Figure 5, the VoIP gateway performs the conversion from a packet data stream into an analog voice signal. This enables users to dial telephone numbers in the gateway's domain. Program solutions such as VocalTec, MediaRing Talk, and others are capable of calling someone outside the IP world. A voice call from User A travels through the Internet to the gateway nearest to User B. This is important because User A pays for a call from the gateway to User B's destination, as well as for the gateway services and his Internet connection.

Phone-to-Phone Configuration

The next step in VoIP evolution was to exploit VoIP gateways at both ends for bidirectional calls. Using such a gateway, users can call each other from analog telephones via IP. If the ISP offers such a service, User A (Figure 6) first dials the ISP's service telephone number, followed by the telephone number of User B. Gateway A translates this number to the IP address of gateway B (the one nearest to User B) and forwards the call. Such a service is particularly appealing to those users who make many expensive international calls and would like to reduce their phone expenses. The price of such a conversation can be very low, at least until ISPs offer quality of service

(QoS), in which case they may start charging customers higher amounts.

To make phone calls using the configuration shown in Figure 6, individuals make use of IP phones that provide considerable benefits. The most important benefit is a reduction in costs in implementing, managing, and maintaining only one network only instead of two. Consider a large company with Intranet implemented on a LAN and with geographically dispersed offices connected through a WAN via leased links. Because leased lines are quite expensive and mostly unoccupied, the transmission of voice over these lines enhances traffic throughput.

VoIP Gateways

Different types of VoIP gateways are being deployed to support VoIP. Some of the popular are described as follows.

PBX-based gateways: Leading manufacturers of PBX equipment are introducing their own solutions to address the VoIP challenge. The drawback is that these vendors have minimal experience in IP-centric data networking. However, the biggest disadvantage of the PBX-based approach is that it is tied so directly to highly proprietary PBX platforms. Leading PBX vendors have no demonstrable track record in either defining or adopting the types of open technical standards that have accelerated adoption of the Internet over the past decade.

Router-based gateways: Manufacturers of routers and other data networking hardware are also getting actively involved in the VoIP market. Unfortunately, router vendors' unfamiliarity with voice technology and call management continues to hamper their abilities to deliver corporate-class telephony solutions. Many of the router-based gateway vendors are steering their customers to end-to-end solutions, which require a single manufacturer's equipment across the edge and core of the network. This approach is precisely the type of lock-in that most technology managers would prefer to avoid during the early stages of their VoIP plans.

PC-based gateways: Several vendors are also bringing stand-alone PC-based gateways to the market. These commercial products offer a router/PBX-independent solution, since they are not tied to a particular manufacturer's platform. However, stand-alone gateways are also typically based on the PC platform, which may not be inherently reliable.

Intelligent multipath switching gateways: A fourth alternative to the gateways discussed above that has recently been introduced on the market is the multipath switch gateway. This device has been designed to address issues not addressed by previous VoIP gateway designs—namely, voice quality, network reliability, and vendor independence.

Multipath voice/data switch: A multipath voice/data switch resides between the corporate PBX and both the PSTN and the corporate IP data network. Its most prominent distinguishing characteristic is its ability to continuously monitor the condition of the data network and to route voice traffic accordingly. This intelligent switching capability is the key to its value for safe, controlled migration to VoIP. If conditions on the corporate network are sufficient to support the required level of voice quality, the gateway switches voice traffic to the appropriate router. If conditions on the corporate network deteriorate for some reason, the switch automatically and transparently redirects voice traffic over the public switched network. Intelligent multipath switching addresses the foremost concerns of both business and technology managers who are considering a first-stage implementation of VoIP.

Voice Coders/Decoders

A coder-decoder (codec) is usually implemented in a digital signal processor (DSP) at a voice gateway or in software running on a desktop computer. The voice codec performs conversions between analog voice and the compressed digital representation of the voice. Coding is done at the entry point to a packet network, and decoding is done at the exit point of the packet network. The voice codec used must be the same at each end of the communication link. Gateways that transport voice over a packet backbone network negotiate with one another via standardized signaling messages to decide on the common codec they will be use. Several factors must be taken into account to evaluate the best voice codec (where "best" refers to the trade-off between optimal quality and bandwidth usage).

Criteria for Voice Codec Selection

The bit rate of current narrowband codecs using today's technology ranges from 1.2 to 64 kbits/s. The most efficient codec available today allows quasi-toll quality (where toll quality is equal to a PSTN telephone conversation). Manufacturers must pay royalty fees to implement some codecs into their VoIP products. This can sometimes lead a vendor's VoIP application to use an inefficient codec that may be cheaper to license. Hence, the issue of royalties is another aspect that needs to be considered when evaluating voice coders in terms of the trade-off between cost and performance. Most narrowband codecs compress voice in chunks (frames) and need look-ahead information; in other words, these codecs require information about the samples immediately following the samples they are currently encoding. The minimal delay introduced by a coding-decoding sequence is the frame length plus the look-ahead size (algorithmic delay). Codecs with a small frame length have a smaller delay than those with longer frame lengths, but they introduce a large overhead. Most implementations choose to send multiple frames per packet; the real frame length to take into account is the sum of all frames stacked in a single IP packet. Another factor that must be considered in selecting a voice codec is packet loss handling. IP does not handle packet loss; if this happens, it affects the operation of the codec. Packet loss can be further exacerbated on the Internet, where several consecutive packets may be lost or dropped. Thus, implementing packet loss recovery may not be productive if the algorithm only protects against intermittent packet loss. Forward error correction (FEC) redundancy can be used to recover from serious loss conditions, but at the expense of delay. Alternatively, multiple send redundancy can be utilized, but it would transmit more packets; if router congestion were the cause, using this technique would not be beneficial. Finally, it is worth pointing out that most codecs used today can only multicast voice at a single level of quality (bit rate). Therefore, it would not be possible to transmit the same data at different quality rates to multiple listeners without sending individual VoIP streams.

The following three International Telecommunications Union (ITU)-based audio codecs are frequently used in VoIP applications:

- **G.711:** The G.711 codec describes a relatively simple way to digitize analog data by using pulse code modulation (PCM). Its goal is to increase the resolution for small signals, whereas large signals are treated proportionally. The encoded stream is 64 kbits/s, consisting of 8 KHz sampling of 8-bit signals.
- **G.723.1:** The G.723.1 codec has been selected as the baseline codec for narrowband H.323 communications by the International Multimedia Telecommunications Consortium (MTC) VoIP forum. G.723.1 is a coded representation that can be used to compress the speech component of multimedia services at a low bit rate (compared to 64 kbits/s for the G.711). The voice coder has two bit rates associated with it—5.3 and 6.3 kbits/s—whose modes of operation can change dynamically at each frame. The frame length is 30 milliseconds; however, another 7.5-millisecond delay is necessary for its

Table 3: Characteristics of Voice Codecs

Codec Type	Algorithm	Frame Size (milliseconds)	Rate (kbits/s)	Mean Opinion Score (MOS)
G.711	PCM ¹	0.125	64	4.1
G.726	ADPCM ²	0.125	32	3.9
G.728	LD-CELP ³	0.625	16	3.6
G.729A	CS-ACELP ⁴	10	8	3.7
G.729e	Hybrid CELP	10	11.8	3.92
G.723.1	MPC-MLQ ⁵	30	6.3	3.9
G.723.1	ACELP	30	5.3	3.65
AMR ⁶	ACELP	20	4.75-12.2	

¹ PCM: pulse code modulation

² ADPCM: adaptive differential pulse code modulation

³ LD-CELP: low delay code excited linear prediction

⁴ CS-ACELP: conjugate-structured algebraic code-excited linear prediction

⁵ MPC-MLQ: Multi-pulse code-maximum likelihood quantization

⁶ AMR: adaptive multi-rate

Source: ITU-T (1998)

look-ahead buffer, resulting in a total algorithmic delay of 37.5 milliseconds. The G.723.1 voice coder encodes speech in frames using linear predictive analysis-by-synthesis coding. The high-rate voice coder uses multi-pulse-maximum likelihood quantization (MP-MLQ), whereas the low-rate coder uses algebraic code-excited linear prediction (ACELP).

- G.729A: The G.729/G.729A voice coder uses conjugate-structured algebraic code-excited linear prediction (CS-ACELP) coding technique (Udani and Mehta 2001). It produces a speech rate of 8 kbits/s, with an algorithmic delay of 15 milliseconds (10 milliseconds of frame length and 5 milliseconds of look-ahead time). G.729A is the reduced-complexity version of the original version of G.729.

A summary of the different types of codecs available for VoIP applications is given in Table 3. The quality of a voice call through a codec is often measured by subjective testing under controlled conditions using a large number of listeners to determine a mean opinion score (MOS). The general order of fixed rate codecs, from best to worst in tandem, is G.711, G.726, G.729e, G.728, G.729, and G.723.1 (Wright 2001).

Performance Metrics for Assessing Voice Quality

Conditions in the PSTN are totally different from those in packet-based networks. The circuit-switched PSTN network provides a separate connection for each voice connection, with stable delay and noise level conditions. However, in a packet-based network, links are shared between different connections, resulting in the interaction between various traffic types. Hence, voice connections over best-effort IP networks are subject to unstable conditions, including unpredictable delays, delay jitter, and packet loss.

Some of the metrics used are described as follows:

- Mean opinion score: this technique uses human judges and perceptual speech quality measurement (PSQM) to evaluate human hearing (Lakaniemi, Rosti, and Raisenen 2001).
- Latency: The end-to-end delay of voice between the source and the destination is an important metric that determines the ultimate quality of voice delivered. A summary of different delay values and their acceptability or unacceptability when compared to delays associated with the delivery of traditional voice over PSTN will be discussed. To ensure good voice quality, latency for voice communications should not exceed 400 milliseconds, as shown in Figure 7 (Goode 2002).

Many processing components add delays during the capture and delivery of the voice to the destination user. The various delay components that constitute the end-to-end delay are shown in Table 4. The “Internet delivery” delay takes into account the delays incurred (e.g., due to network devices such as routers become overloaded, congestions over communication links, packets taking more hops than normal and thereby increasing the travel time over the network) as packets are transported through the Internet. It is important to point out that high end-to-end delays lead to echoes; the greater the delay, the more offensive the echoes become, and the more important it is to deal with them effectively. If packets containing voice do not arrive within a reasonable time, they are dropped and a condition known as *clipping* (the cutting off of the first or final syllables in a conversation) occurs.

To overcome the effects of high latency, a class of service (CoS) or QoS can be assigned to various applications running over the network. For instance, voice and other multimedia applications can be recognized as time sensitive and therefore take priority over other, less time-sensitive media types. QoS over the Internet and corporate

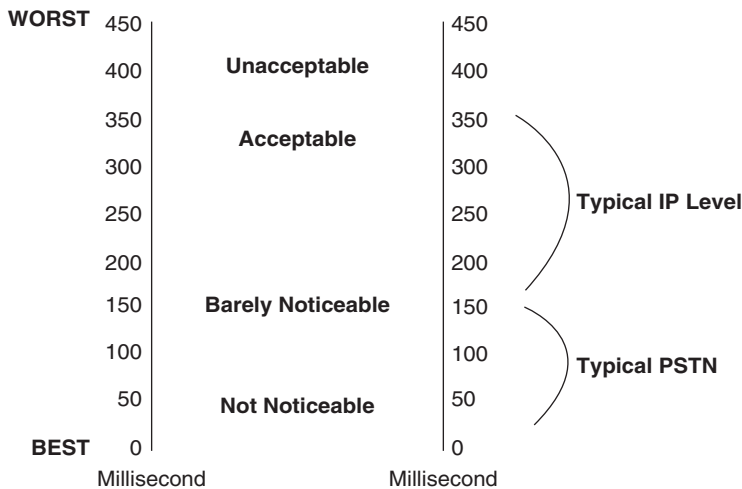

Figure 7: Voice delay levels (milliseconds)

Table 4: End-to-End VoIP Packet Delay

Processing Delay	Delay (milliseconds)
Recording	10–40
Encoding	5–10
Compression	5–10
Internet Delivery	70–120
Jitter Buffer	50–200
Decompression	5–10
Decode	5–10
Average end-to-end delay (sum of all individual delay components)	150–400

Source: Kampichler and Goeschka (2001)

intranets is handled by routers and switches that implement various resource reservation (e.g., bandwidth) techniques: IntServ, Diffserv, and multiprotocol label switching (MPLS; Mahadevan and Sivalingam 1999; Rouhana and Horlait, 2000). Currently, QoS is easier to apply on corporate intranets in which a single company has complete end-to-end control over the network. Applying QoS over the public Internet is a lot harder because it requires the cooperation of many ISPs, which do not all have QoS-enabled routers and switches. Therefore, we are still relying on best-effort delivery provided by the Internet for most delay-sensitive media types such as voice and video.

- **Delay jitter:** IP networks do not guarantee the delivery time of data packets (or their order), so data may arrive at inconsistent rates. The variation in interpacket arrival rate is known as *jitter*, which is introduced by variable transmission delays over the network. Jitter buffers can be used to remove the packet-delay variation that each packet is subjected to as it travels through the network.

- **Packet loss:** For VoIP, packet loss leads to lost portions of speech that results in poor voice quality. The total packet loss experienced by the receiver in the case of wired networks has two components: packet loss occurring in the network because of congestion at some intermediate node(s), and at the receiver because of packets arriving later than their scheduled playback times. However, in the case of wireless environments, packet losses may occur as a result of several other causes such as handoffs, interference, fading of wireless signals, and so forth. Some packet loss is tolerable; for example, many voice encoders can handle up to 1 percent packet loss (Wright 2001). Since the emergence of the concept of packetized voice in the late 1970s, extensive work has been undertaken to reduce packet loss and its effects.
- **Coding distortion:** Before voice is transmitted over an IP network, the voice signal must be encoded to fit into the available bandwidth. Voice codecs such as G.723.1 and G.729 are the most commonly used. These algorithms are efficient in keeping the bandwidth consumed by a voice call to a minimum. However, the quality of voice generally degrades when high compression ratios are used. Some algorithms are better at maintaining voice quality than others. For example, the ITU's G.711 algorithm provides toll-quality voice by converting a 16-bit linear code to an 8-bit U-law or A-law code. However, G.711 uses 64 kbits/s of channel capacity, which is considered too much for a VoIP system. New algorithms such as G.723 and G.729 consume much lower bandwidth but reduce voice quality to some extent. Efforts are constantly under way to find algorithms that can boost compression ratio while maintaining high voice quality.

VoIP Protocols and Standards

VoIP requires a connection between users—in the case of VoIP, a virtual connection. As mentioned earlier, a VoIP architecture includes many components. First, a signaling protocol is needed to set up individual sessions for voice connections between users. Once a session is established, a transport protocol can be used to send the data

packets. Directory access protocols are another important part of VoIP, providing routing and switching information for connecting calls. A signaling protocol handles user location, session establishment, session negotiation, call participant management, and feature invocation. Session establishment is invoked when a user is located, allowing the call recipient to accept, reject, or forward the call. Session negotiation helps to manage different types of media, such as voice and video, transmitted at the same time. Call participant management helps to control users who are active on the call, allowing for the addition and subtraction of users. A signaling protocol also involves feature invocation and call features such as hold, transfer, and mute. Various signaling protocols recently developed can also be used to support VoIP transmissions. Two of the most popular signaling protocols are discussed as follows.

H.323

The H.323 standard (Glasmann and Keller 2001) is the ITU's standard with which vendors need to comply when providing VoIP services. The standard was originally developed for multimedia conferencing over LANs but was later extended to cover VoIP. The first version was released in 1996, and the second version of H.323 came into effect in January 1998. The standard encompasses both point-to-point communications and multipoint conferences. The products and applications of different vendors can interoperate if they abide by the H.323 specification. H.323 defines four logical components: terminals, gateways, gatekeepers, and multipoint control units (MCUs); these provide the capability for three or more terminals and gateways to participate in a multipoint conference). Terminals, gateways, and MCUs are known as end points.

Session Initiation Protocol

Session initiation protocol (SIP) is an application-layer control protocol that can establish, modify, and terminate multimedia sessions such as multimedia conferences, Internet telephony calls, and similar applications with one or more participants (Handley et al. 1999). The basic role of SIP is to locate and invite participants to a multimedia session that could range from a VoIP call to text chat, application sharing, video, and so forth. A participant in an SIP session could be a human user or an automaton, such as a media server, or even a gateway to some other network, such as the PSTN. SIP also provides a rich framework of other telephony services including user location, forward, transfer, multiparty, mute, and hold. It also supports certain advanced features such as interactive voice response systems and a form of mobility. The architecture of SIP follows the client-server model and is similar to that of HTTP with requests issued by the client and responses returned by the server. With regard to VoIP calls, the caller acts as the client and the callee as the server. A single call may involve several servers and clients because the requests may be forwarded. SIP supports the following features that enable the establishment and teardown of VoIP calls:

- User location: discovery of the location of the end system from which the user wishes to communicate
- User availability: determination of the willingness of the called party to engage in communications
- User capabilities: negotiation and determination of the various media parameters to be used by the caller and the callee
- Call setup: establishment of call parameters and flow of media streams
- Call handling: termination of call sessions, transfer of calls, and invocation of other services

SIP is text based and works independently of the underlying transport and network layer protocols. SIP uses a simple signaling scheme to handle only the basic requirements such as the creation, modification, and termination of sessions. This simplicity helps in the rapid call-setup, which is crucial for high QoS.

SIP message types. An SIP message—the basic unit of SIP communication—is either a request from a client to a server or a response status code from a server to the client. Six methods exist by which SIP requests can be made:

- INVITE: indicates that a user or service is being invited to participate in a session
- ACK: confirms that the client has received a final response to an INVITE request; provided for reliable exchange of invitation messages
- BYE: used by the user agent client (UAC) to indicate to the server that it wishes to release the call; may be issued by either the caller or the callee, and is basically used to terminate a connection between the two end points
- OPTIONS: solicits information about a user's capabilities
- REGISTER: gives information about the location of a user to the SIP registration server; used by an SIP client to register its address with the registration server
- CANCEL: used to cancel a pending request; may be issued by the user agent client or the proxy client

Related Works on SIP-Based VoIP Systems

Efforts to implement SIP features for VoIP services have been under way for the past few years. Hyun, Huh, and Kang (2002) address the design and implementation of SIP server components such as proxy and registrar server. Their implementation supports call forking, authentication, and a stateful proxy nature. Huh et al. (2002) describe the implementation of a user agent system for voice services; the features supported include call establishment, termination, registration, and capability negotiation. Zou et al. (2000) present a Java-based implementation of SIP components that focuses primarily on PC-to-PC communication within the context of a virtual private network (VPN) service. As VoIP continues to compete with the PSTN in providing advanced voice communication features, implementing high-level features in IP-based voice service architecture that would further enhance its usability and make it a viable alternative to circuit-switched calling is desirable.

The authors have developed an SIP-based VoIP system that: 1) supports a point-to-point VoIP call with the added

Figure 8: General architecture of the SIP-based VoIP system

capability of transitioning to a multipoint conference; 2) provides a rich set of extensible call-related features using the lightweight SIP protocol; 3) and supports call-related features such as call muting and call-hold facility as well as personal mobility. Personal mobility provides users with the freedom to move and still be able to access the telecommunication services regardless of the terminal or the network.

Our implementation differs from past SIP-based VoIP systems in that our design further extends the SIP component capabilities to support multiparty user interaction compared to only two-participant calls supported by previous efforts. In addition, our prototype SIP-based VoIP implementation provides support for personal mobility and offers additional features, which include multiple audio encoding formats (e.g., G.711 U-law [CCITT 1972], G.726-7 adaptive differential pulse code modulation [ADPCM], and linear PCM).

Implementation of an SIP-Based VoIP Architecture

Our SIP-based VoIP architecture, shown in Figure 8, is implemented and deployed on Sun Ultra-10 workstations running Solaris 8 and connected to a 100 mbits/sec ethernet LAN. The main components of our implementation constitute user agents (UAs) and SIP network servers:

User agents: Each UA consists of a user agent client (UAC) and a user agent server (UAS). The UAC is a logical entity for creating new SIP requests. The UAS is responsible for receiving SIP requests and sending the corresponding responses, along with suitable processing of those SIP requests. In addition, the UAS is capable of functioning either as a caller or a callee.

SIP network servers: These include the registrar server and a proxy/redirect server. The registrar server receives updates from users about their current addresses and sends an appropriate response message back to the user after the registration process. The registrar

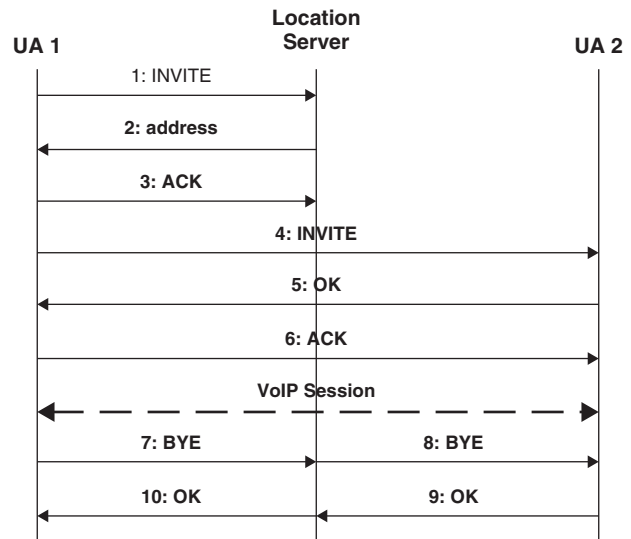

Figure 9: Call flow for a two-participant VoIP call

server thus maintains the current location of each user in the form of a database. The proxy/redirect servers are responsible for routing SIP messages. Our software implements a single location server that collectively implements the functions of the aforementioned servers.

Conference server: Has been implemented to provide multipoint communication support. Our prototype implementation allows point-to-point and multipoint real-time audio interaction between two or more SIP UAs. In addition, our architecture supports all basic communication handling features such as inviting users for call setup, acknowledging requests, canceling pending invitations, and call teardown messages. Additional functionalities such as personal mobility of clients, multiparty conference support, message retransmission, and authentication are also supported.

Figures 9 and 10 briefly demonstrate call flow establishment in our implementation for a two-participant call and a multiparty, respectively. The location server implements the functions of the SIP network servers.

Software components of the SIP-based VoIP architecture. Each UA in our implementation consists of several modules that interact with one another through well-defined interfaces. Figure 11 shows the architecture of the UA system.

UDP is used to transfer SIP messages through configured UDP ports. Each outgoing message is associated with a timer value, the expiration of which triggers a retransmission. UDP is also used to deliver audio packets during a voice call. When an SIP message is received, the parser module parses it and the values interpreted are passed to the UA server for an appropriate response. An outgoing message is composed by the message generator and transmitted using UDP. An audio codec module has also been implemented to compress and decompress voice packets. The audio codec supports different types of compressions (e.g., G.711 U-law, G.726 ADPCM, and

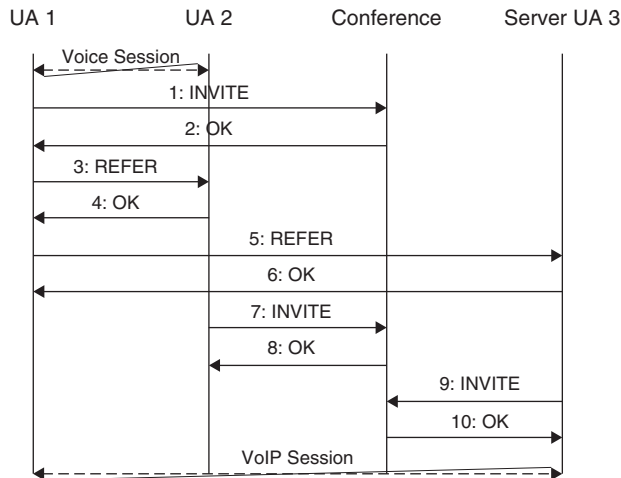

Figure 10: Multiple participant conferencing using the ad hoc centralized conference during a VoIP session

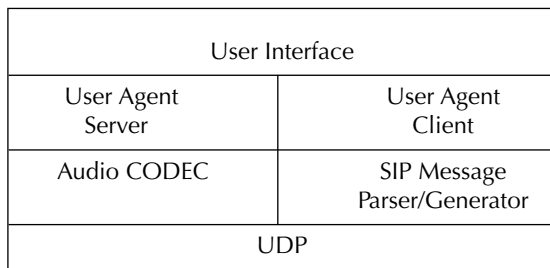

Figure 11: UA modules implemented

linear PCM). The UAS is a continuously running thread that waits for incoming SIP messages. Each request received is handled by the creation of a new thread, thereby making the user agent capable of concurrent processing. Finally, the user interface enables a user to log into the system and make choices to initiate, accept, or reject calls.

The proxy/location server consists of a server thread that listens to incoming requests from other SIP entities. Upon receipt of an SIP message, the SIP parser function is called to interpret the message for processing. This component has been designed to support the functions of registering new users, retrieving current user locations by querying the associated database, and signaling call teardown to participating users.

Multiple-participant VoIP conference support. Our implementation also supports multiparty audio interaction among users (Rosenberg and Schulzrinne 2000). This feature allows the addition of further participants during an ongoing two-participant session. To accomplish this, the ad hoc centralized conferencing model has been exploited in our design.

The first step toward the transition is the discovery of a conference server. In this implementation, the conference server's address is specified in the user-agent source code. This allows any participant of an ongoing call to invite a new participant to join a session. The caller first sends an INVITE message to the conference server. The server

replies with an OK message and sends a new conference identifier assigned to the new session (involving the additional participant). The inviter then issues REFER messages (containing the new conference identifier) directly to the other participants. These participants in turn send INVITE messages to the conference server. When each participant receives the acknowledgement from the conference server, a voice conference session is established.

The conference server supports two main functions. First, it maintains a list of conferences and their corresponding participants. Second, it performs redistribution of incoming audio data to each participant. For a centralized conferencing model such as the one adopted in our prototype, the conference server receives voice packets from n participants and retransmits $(n-1)$ streams to each user; it does not retransmit a source's own packets back to itself again. Figure 12 shows the underlying idea of the centralized conference server. When a user wishes to leave a conference, it issues a BYE message and quits. The conference session is terminated when the last participant leaves.

Our architecture differs from other centralized audio conferencing schemes (Wang, Zhang, and Li 2000) previously implemented in its support for personal mobility through registration and redirection services performed by the location server.

Personal mobility. Personal mobility provides users with the freedom to move and yet be able to access the telecommunication services regardless of the terminal or the network. To support personal mobility, our implementation uses a combination of a user's personal identity and location tracking performed by the location server.

A location server is used to keep track of the location of each user (i.e., from which terminal a user is working). From a user's perspective, personal mobility is obtained by logging on to the network through some terminal (using a designated personal identity, which is assigned the first time the user accesses the service) and then being able to make and receive calls from the terminal from which he is logged on. When a user on any terminal logs on to a network, SIP messages are sent to the location server, which records the IP address from which the entry was made. Thus, each time the user signs into the system through the UA, an SIP message is immediately sent to the location server to register its current location into the database for future lookup requests by potential callers. The user location is purged from the list after disconnecting from the service and reentered if the user registers again from a new location. This feature makes the application independent

Figure 12: Packet redistribution by a conference server

Table 5: Variation of Interarrival Packet Delays

Encoding Format	Variation of Interarrival Packet Delays (milliseconds) with Number of Participants		
	2	3	4
U-law	64	158	169
ADPCM	16	52	77
Linear PCM (uncompressed)	8	28	51

of the IP address of the participating users' terminals, allowing the user to access the service independent of the location.

The use of a personal identity in our implementation is further complemented by a password corresponding to each identity, thereby making the service accessible to authenticated users only.

Performance with SIP. The impact of increasing numbers of participants and different types of voice-encoding formats on interarrival VoIP packet delays (as shown in Table 5) were measured. The encoding formats used include linear PCM, ADPCM, and U-law. Linear PCM is an uncompressed audio format in which each audio sample is stored using 16 bits, thereby requiring 128 kbits/s of bandwidth ($16 \text{ bits/sample} \times 8000 \text{ samples/sec}$). With regard to U-law, voice is compressed to 8-bit samples, thereby reducing the bandwidth to 64 kbits/s. A further reduction in the bandwidth requirement was obtained by using the International Multimedia Association (IMA)-ADPCM algorithm, which compresses linear PCM samples into 4-bit quantization levels. Each ADPCM sample represents a 16-bit audio sample providing a compression ratio of 4:1 and yielding a bit rate of 32 kbits/s. The interarrival delay was calculated as the difference in arrival times of two consecutive packets at the receiver host. The measurements were taken for one-way transmissions and repeated several times for each participant, and average values were recorded.

As observed from the values recorded, the interarrival packet delay is lowest for a two-participant session and increases almost linearly with the increasing number of participants. The transition from a two-participant session to a multiparticipant session causes a slightly higher increase in delay because packets need to go through the conference server to the destination (in the latter case). Lower packet-arrival delays were obtained using the linear PCM and ADPCM formats as compared to the U-law encoding format. However, the linear PCM format has a higher bandwidth requirement than the ADPCM and U-law formats.

Benefits of SIP Compared to H.323

SIP provides a set of services similar to H.323. However, SIP offers major benefits over H.323 in terms of lower complexity, rich extensibility, and better scalability (Schulzrinne and Rosenberg 1998):

- **Complexity:** H.323 is a rather complex protocol. The sum total of the base specifications alone is over

700 pages; SIP, on the other hand, even with its call control extensions and session description protocols totals merely 128 pages. H.323 also defines several hundreds of elements, whereas SIP has only 37 headers, each with a small number of values and parameters that contain more information. H.323 uses a binary representation for its messages, based on ASN.1 and the packed encoding rules (PERs). ASN.1 generally requires special code generators to parse. SIP encodes its messages as text, similar to HTTP, which leads to simple parsing and generation. H.323's complexity also stems from its use of several protocol components. There is no clean separation of these components; many services require interactions between several of them. SIP, on the other hand, uses a single request that contains all necessary information.

- **Extensibility:** With regard to H.323, adding new elements, features, and headers and managing compatibility across different versions is not easily done. A critical issue involves audio and video codecs; SIP uses the session description protocol (SDP) to convey the codecs supported by an end point in a session and is capable of working with any codec. H.323, however, can only work with a small number of standardized ITU speech and video codecs.
- **Modularity:** SIP is a reasonably modular protocol compared to H.323. It encompasses basic call signaling features such as user location and registration. Advanced features such as directory accesses, service discovery, session content description, and so forth are orthogonal and reside in separate protocols. Conversely, H.323 defines a vertically integrated protocol suite for a single application. The mix of services provided by the H.323 components is intertwined within the various subprotocols it contains, thereby making H.323 less modular.
- **Scalability:** H.323 is not very scalable because it was originally designed for use on a single LAN; as a result, it has certain problems in scaling (newer versions have suggested techniques to get around the problem). H.323 is still limited when performing loop detection in complex multidomain searches. It can be done statefully by storing messages, but this technique is not very scalable. SIP uses a loop detection method by checking the history of the message in the header fields, which can be done in a stateless manner.

Other Supporting Protocols

SIP can be used with other IETF protocols to build a complete multimedia architecture, though a discussion

of such protocols is beyond the scope of this chapter. Some of these protocols include: resource reservation protocol (RSVP; Komolafe and Sventek 2005), real-time transport protocol (RTP) and real-time control transport protocol (RTCP; Ping, Wenjuan, and Haifeng 2005), real-time streaming protocol (RTSP; Schulzrinne, Rao, and Lanphier 1998), session announcement protocol (SAP), and session description protocol (SDP). RSVP is used for reserving resources, RTP/RTCP for transporting real-time data, RTSP for controlled delivery of streams, SAP for advertising multimedia sessions, and SDP for describing multimedia sessions. H.323 also works in conjunction with RTP and RTCP.

EMPIRICAL VOIP RESULTS

In this section, we present some empirical VoIP performance results of a simple VoIP system we have designed and implemented.

Experimental Setup

The implemented VoIP software (shown in Figure 13) allows the use of compressed or uncompressed voice on the Solaris 8 operating system running on Ultra SPARC workstations (each with an Ultra SPARC- II i440 MHz processor and 512 MB RAM). The machines were connected through an IP network, and VoIP connections were set up in a real networking environment.

On the sender's side, analog voice was given as input through a microphone. This was sampled at a rate of 8 KHz. Voice was then transmitted in UDP packets over the network, in both uncompressed (linear PCM) and compressed (G.711 U-law and G.726-7 ADPCM) formats. On the receiver's side, the voice samples were retrieved from the UDP packets, decompressed (in the case of compressed samples), and put in the playout buffer of the sound card, which was played back and listened to by the end user through a headset connected to the receiving host.

Measurement Procedures

We used two identical machines with the configurations described above for all experiments performed to eliminate variance in delays that may occur as a result of hardware differences. The implemented VoIP software was

executed at the sender and receiver hosts. All real-time VoIP tests were conducted during daytime hours. The packet size used in the VoIP transmission tests was 200 bytes. Experimental tests measured the following metrics that affect the ultimate quality of voice delivered to the end user:

- **End-to-end delay:** For the VoIP system, this was calculated by the sum of all delays contributed by each individual component (recording, compression, transmission, decompression, and playback). Measuring the delay introduced by the different components in the end-to-end delay path identified components that introduce high delays and bottleneck areas. The network transmission delay was measured by sending a voice packet from the sender to the receiver and making the receiver echo it back to the sending host. Time was recorded before transmission and after reception at the sending host. The time difference yields the round-trip time (RTT), which—when halved—gives the one-way transmission delay.
- **Interarrival packet delay:** This was calculated in terms of differences in the arrival times of two consecutive packets at the receiver host. Each voice packet received at the receiver node was immediately time stamped (T_i); the difference between two consecutive time stamps of two consecutive packets gives the interarrival packet delay of $D_i = T_i - T_{(i-1)}$.
- **Jitter:** This was calculated as the difference between the average of the interarrival delay (D_{AVE}) and the individual interarrival delay (D_i).

End-to-End Delay Performance

Influence of Delay Components on End-to-End Performance

The total end-to-end delay between the source and destination consists of different delay components: recording, compression, transmission delay (includes packetization and network delays), decompression, and playback. As the results in Table 6 illustrate, ADPCM yields end-to-end delays close to uncompressed (PCM) voice; this is because the compression delay introduced by ADPCM is very small (approximately 0.13 to 0.23 milliseconds, depending on the packet size used). In addition, with ADPCM,

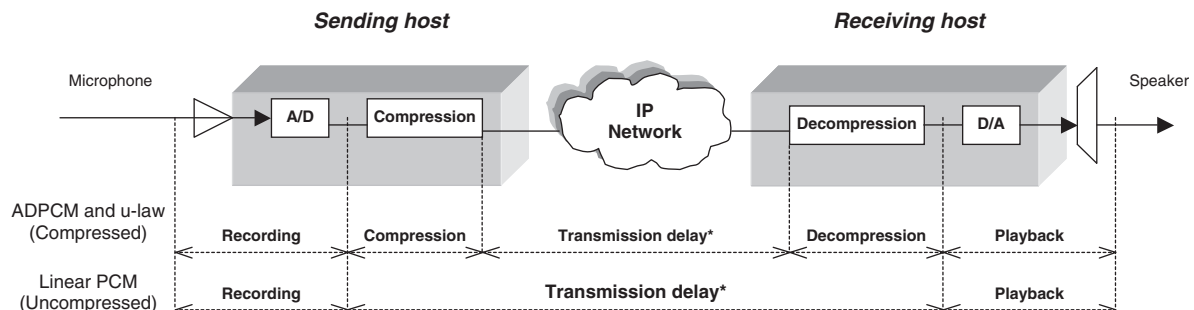

Figure 13: Delay components of our implemented VoIP system. The transmission delay includes the delay involved in transferring the packet between the voice application and the physical network (at sender and receiver) and the network delay

Table 6: A Breakdown of the End-to-End Delay Components with VoIP Packets of Size 200 Bytes¹

Delay Component	Linear PCM	ADPCM	U-Law
	Time (milliseconds)	Time (milliseconds)	Time (milliseconds)
Recording	12.5	12.5	12.5
Compression	0 (0%)	0.20 (1.20%)	12.4 (42.5%)
Transmission	3.99	4.04	4.05
Decompression	0 (0%)	0.13 (0.76%)	0.08 (0.30%)
Playback	0.13	0.13	0.13
Total End-to-End Delay	16.62	17.0	29.16

¹ The transmission delay includes the delay involved in transferring the packet between the voice application and the physical network (at sender and receiver) and the network delay. The percentage of the delay overhead of the total end-to-end delay due to compression and decompression is also shown in parentheses.

the compression delays and decompression delays are almost the same, though the compression delays are slightly higher. Compression and decompression delays with ADPCM account for 1.2 percent and 0.76 percent of the end-to-end delay, respectively. However, with U-law compression, compression delays (42.5 percent of the end-to-end delay) were much higher than decompression delays (0.30 percent).

U-law not only gives higher compression-decompression delays but also yields a higher bit rate (64 kbits/s per voice channel) than the bit rate that results from ADPCM (32 kbits/s per voice channel). One may wonder why U-law should still be used at all if ADPCM is preferable in these two respects. However, although the voice quality of both is acceptable in these cases, in terms of output speech quality, MOS scores from previous experiments (Hagsand, Hanson, and Marsh 1999) found that a slightly better voice quality is obtained with U-law than with ADPCM; the compression-decompression process performed by ADPCM causes a slightly larger voice distortion than does U-law.

Interarrival Packet Delay

Figure 14 shows the variation of mean interarrival packet delays with packet sizes. The results show that linear PCM yields on average the lowest interarrival delay and U-law the highest. In contrast to the close end-to-end delay values obtained for PCM and ADPCM, the results for interarrival packet delays for ADPCM on average tend to be slightly higher than those with PCM.

Jitter

Table 7 shows the jitter obtained at the receiver host when voice is delivered to the end user. A mean jitter

**Figure 14:** Variation of interarrival packet delay with voice packet size using linear PCM, ADPCM, and μ -law

of approximately 7 to 9 milliseconds was obtained for ADPCM and μ -law (twice the mean jitter obtained with PCM).

VOIP OVER WIRELESS LOCAL AREA NETWORKS

Wireless Local Area Networks (WLANs) are frequently used as extensions to the wired Internet. Internet applications that have traditionally been deployed and executed on the wired infrastructure are increasingly being deployed over WLANs (IEEE 802.11a/b/g) as well because of WLANs' convenience in terms of mobility and wireless access. WLAN represents an important trend for

Table 7: Minimum, Maximum, and Mean Jitter Values at the Receiver Using a Voice Packet Size of 200 Bytes

CODEC Type	Minimum (milliseconds)	Maximum (milliseconds)	Mean (milliseconds)
PCM	0.08	20.3	3.4
ADPCM	2.9	32.7	8.2
μ -law	4.7	17.4	7.5

“last-mile” Internet access (Wang, Chang, and Li 2005) and will be expected to support popular Internet applications such as VoIP. In fact, the convergence of VoIP and WLAN technologies has led to the creation of an important Internet application called Voice over WLAN (VoWLAN). However, before a standard VoWLAN solution can be completely deployed, several technical issues including system capacity, voice quality, roaming latency, and security need to be addressed.

VoIP Transmission Schemes over WLANs

Different methods can be used for voice transmissions over a WLAN (Prasad 1999):

- **Distributed coordination function (DCF):** DCF is a contention-based access method. A station (client) that is ready to transmit a frame will sense the medium; if the medium is busy, it will wait for an additional predetermined time period of DCF interframe space (DIFS) length. During the contention window period, WLAN stations calculate the random back-off time by multiplying the time slot picked up in the window by a random number. A WLAN station ticks down the random back-off time, checking if the medium is busy. The station with the shortest time gains access to the medium first and transmits its frame. The collisions can now occur only when two or more stations select the same time slot to transmit. These stations will have to reenter the contention procedure to select new time slots to transmit the collided frames (Wang et al. 2005).
- **Point coordination function (PCF):** PCF is specified in the 802.11 standard as an optional protocol framing method. PCF was designed to accommodate those services requiring both voice and data transactions. The frame-slotting structure of PCF is viewed as a master-slave infrastructure network. The access point (AP) is the point coordinator (PC) for a given coverage area. The coverage area is commonly referred to as basic service area (BSA). The AP is the master controller and the stations are the slave radios in a BSA. The PC maps a prioritizing scheme and determines which radio has the right to transmit. The access priority given by the PCF is used to create the contention-free (CF) period. At the beginning of the CF period, the AP transmits a beacon frame that contains the maximum duration of the contention-free period (CFPMaxDuration). All stations receiving the beacon set the network allocation vector (NAV) to the maximum duration to lock out DCF-based access to the wireless medium. During this period, all slave radios are polled in a slotted fashion. At the beginning of the CF period a beacon is broadcast to the slave radios, assigning priorities. The radio with the highest priority is polled first. The slave radio responds with the data “piggyback” of a special acknowledgement (ACK) just after a short inter-frame space (SIFS) timeout. Each slave radio is polled in priority until the NAV and CF period has expired. The timing of the slave radios is synchronized by resetting the NAV timer located in the media access control (MAC) layer; this is set at the beginning of each CF interval. The CF interval polling process is repeated from then onward. All transmissions in the CF period are generally separated by the SIFS.

To ensure that the point coordinator retains control of the medium, it may send to the next station on its polling list if no response is received after an elapsed PIFS (Prasad 1999).

- **Priority queuing:** Priority queuing is a scheme that gives voice packets priority over data packets within a system. The channel access process remains the same as in a WLAN except that the random back-off value is varied for voice and data transmissions.
- **Blackburst:** Blackburst is a multiple-access scheme for voice communication that can be overlaid on an IEEE 802.11 implementation. This scheme uses carrier sense capability, as in IEEE 802.11, and only requires the ability to jam the channel with pulses of energy of specified duration. Using this process the voice stations appear to access the channel in a time division multiplexed fashion, which is perturbed and repositioned by data packet transmission. Mixed populations of data and voice stations share a common radio channel in the Blackburst design. The data stations regulate their access to the channel according to the carrier sense multiple access with collision avoidance (CSMA/CA) protocol, and the voice stations follow a variation of CSMA/CA that will give them priority over data stations.

VoIP over WLAN Issues

Impact of WLANs on VoIP Transmissions

The convergence of voice and data networks enables new applications as well as saving benefits. However, there are several restraining factors that make the delivery of voice over WLANs particularly challenging. Some of those factors are as follows:

- **Excessive latency, jitter, and degraded voice quality:** One of the major differences between VoIP applications and data applications is the sensitivity to latency (transmission delays). Data applications (e.g., Web, e-mail, file transfers) are much less sensitive to latency than reduced throughput. A delay of seconds in receiving a data file is normally acceptable; however, a latency of tens of milliseconds in a voice call is very noticeable, annoying, and typically intolerable. As a comparison, TCP/IP has a maximum latency of 120 seconds (Wang et al. 2005), whereas the ITU G.114 recommends a maximum one-way latency of 150 milliseconds for voice calls.
- **Another difference between VoIP applications and data applications is the sensitivity to jitter.** Jitter refers to random variations in latency. Jitter in a voice call is readily audible as clicks, pauses, or unintelligible speech. Jitter buffers are used to overcome the effects by turning jitter into a longer constant latency; this is accomplished by buffering received voice packets and delaying their decoding. The jitter buffer adds delay according to the slowest packet (largest latency), creating substantial additional latency. Every transmitting and receiving node in the network, such as the AP in a WLAN, typically buffers incoming and outgoing packets. This causes latency and jitter. The overheads of roaming, security mechanisms, retransmissions, and data and voice convergence add latency and jitter in WLAN environments. These factors are discussed as follows.

- **Poor coverage:** One of the advantages of VoIP over WLANs is that no wiring is required, thereby providing the freedom of mobility. To enable callers to move around the enterprise freely, however, their connections must be maintained without interruption. That is, to have true mobility, coverage must be ubiquitous and continuous throughout the enterprise. Traditional topologies based on cell planning cannot provide continuous coverage at the maximum data rate. The limited numbers of channels result in limited overlap between cells, creating shadows, or “black holes” (areas of poor or no coverage). In addition, interference and obstructions make it difficult to provide uninterrupted voice service even in a single cell.
- **Roaming latency and interruptions in voice service:** Traditional WLAN topology uses cell planning to achieve coverage. As mobile users move from one cell to another, handoffs between access points (also known as inter-AP handoffs) are required. As the cell size decreases to provide capacity, inter-AP handoffs occur more frequently. A handoff requires several steps, including AP discovery, re-association, security measures, and higher-level protocol exchanges. AP discovery typically takes 150–400 milliseconds and introduces 40–100 milliseconds of jitter in 802.11b and 802.11g, which exceeds acceptable voice latency. AP discovery latency and jitter in 802.11a or in multimode networks may be twice as high or more (Wang et al. 2005).

A reassociation consists of several steps, including station-to-AP handshake, inter-AP protocol, inter-access point protocol (IAPP) exchanges, and bridge notification. Each step introduces additional latency and jitter, and security measures introduce even more. Higher-level protocol exchanges can also introduce several seconds of latency and result in temporary disruption of service. The exact amount of latency depends on network configuration.

Traditional topologies place the burden of inter-AP handoffs on the client. Clients who are unaware of the network topology frequently make the wrong choices. A WLAN client requires a long time to select an AP and tends to remain with an AP, even if it is far away. Because the handoff is controlled by the client, new solutions that provide AP topology awareness only marginally improve the described latency and jitter. Slow handoffs, or handing off to a nonoptimal AP, result in rate adaptation, which introduces more latency and jitter, reduces capacity, and increases power consumption. Packets buffered in the previous access point may be dropped, degrading the voice quality.

Recent research efforts have begun to focus on reducing inter-access point handoff delays. In particular, IEEE has finalized the IAPP for inter-access point communication. The IAPP, as standardized in IEEE standard 802.11f (2003), enables (fast) link layer reassociation at a new access point in the same hotspot. On the network layer, similar efforts are ongoing in the IETF Seamoby group, which defines different protocols to reduce network discovery and reconfiguration delays.

Security Issues for VoIP over WLANs

Wired equivalent privacy (WEP; Majstor 2003), the original security protocol for 802.11 wireless networks, is now considered flawed by the industry. The IEEE 802.11i

standard introduced newer security standards for WLANs. The interim WiFi protected access (WPA; Majstor 2003) includes temporal key integrity protocol (TKIP), message integrity checks (MIC), and strong authentication through the extensible authentication protocol (EAP), thereby addressing several of the security problems of WEP. Although WPA is necessary to provide adequate security, it introduces an additional overhead for each inter-AP handoff. WPA requires strong authentication mechanisms, along with exchange of pair-wise (AP to station) keys. These processes typically introduce a latency of 500–1500 milliseconds (Wang et al. 2005), potentially resulting in disrupted services. Until better solutions are introduced, voice over WLAN deployments are typically without any security at all. This lack of VoIP security may be responsible for the reluctance of VoIP adoption for an enterprise deployment.

Retransmissions and Dropped Packets over WLANs

Data applications do not tolerate dropped packets; TCP/IP retransmits erroneous or missing packets to avoid data corruption. However, due to TCP/IP's slow start mechanisms, a drop rate of 1 percent or above will result in a severe degradation of throughput. Unlike data, voice can tolerate some packet dropping, typically around 4 to 5 percent (Prasad 1999), as long as the dropped packets are not consecutive. The wireless medium can be quite unreliable; as a result, the WLAN standard includes a retransmission mechanism to avoid dropped packets. Unfortunately, although this is a good solution for data, it results in a significant amount of jitter and latency for voice applications that require timely arrival of packets. To minimize retransmissions in voice applications, a low drop rate is required. This is impossible using traditional network topologies: large distances from APs, temporary and random interference, obstructions, and co-channel interference caused by neighboring cells all cause poor reception of packets with these topologies. Radio frequency (RF) technologies at neighboring organizations or sites may add another source of interference, which may also lead to poor packet reception. Without retransmissions, a large drop rate and consecutive dropped packets occur. With retransmissions, significant latency and jitter are experienced, and the capacity is greatly reduced. In either case, voice quality can be severely affected and require solutions that address the issues mentioned previously.

Low Capacity, Reduced Number of VoIP Calls

Although the major requirements for voice are low latency and jitter, the need for adequate capacity is also important. Capacity determines the number of concurrent calls that can be supported. Given that VoIP typically uses small packets with large overheads, the usual methods of measuring network capacity do not apply to voice. A more relevant measure of capacity for voice applications is the number of packets per second (PPS) that can be transferred. Several factors limit the PPS over a WLAN, the most important of which are contention windows, acknowledgment packets, retransmissions, and rate adaptation. The proposed IEEE 802.11e standard reintroduces contention-free access (scheduled access), termed the hybrid coordination function (HCF). Similar to the

original 802.11 PCF, HCF replaces client competition for airtime with centralized client polling. By avoiding contention, contention-free access methods typically utilize 75 percent of the maximum bandwidth (compared with 37 percent for contention-based access methods; Wang et al. 2005). Contention-free access provides a higher PPS, resulting in an increased number of voice calls that can be supported. Unfortunately, PCF was never supported by mobile clients, and client support for HCF is not yet available. Even if scheduled access will be supported (which is not yet certain), multiple co-channel APs are bound to cause interference, making it difficult to use scheduled access in cell-planning-based topologies. Acknowledgment packets are one of the most significant causes of PPS reduction for voice over WLAN applications, and can account for 30 to 40 percent of the airtime used in a single VoIP packet transfer (Wang et al. 2005). If retransmissions can be avoided and a low drop rate maintained, the need for ACK packets can be eliminated. Unfortunately, retransmissions and the resulting lower-network PPS are unavoidable in traditional topologies. All the restrictions mentioned earlier limit the number of voice calls that can be simultaneously supported over an IEEE 802.11b network (typically five to seven voice calls; Wang et al. 2005).

Quality of Service for Voice and Data Convergence

Converged voice and data networks pose additional challenges to the deployment of voice over WLANs. Although voice applications consume low bandwidth per call, they do require very low latency and jitter. When the network load is high, data packets (typically much larger than voice packets) may use up a significantly high amount of airtime, causing sharp increases in latency and jitter for the voice packets. Typical deployments will prefer good voice quality even if it means lower bandwidth for data. The 802.11e task group has proposed QoS extensions to the 802.11 standard to provide a mechanism for giving higher priority to voice packets over the shared wireless medium. Until the standard is ratified, a subset of the standard, WiFi multimedia (WMM), is being tested. The proposed mechanisms are required in converged voice and data networks to provide acceptable voice quality. However, for such mechanisms to be truly effective, all clients in the WLAN need to support these extensions.

IEEE 802.11e

IEEE 802.11e (2006), as of late 2005, has been approved as a standard that defines a set of QoS enhancements for LAN applications, in particular the 802.11 WiFi standard. The standard is considered of critical importance for delay-sensitive applications, including voice over wireless IP (VoWIP) and streaming multimedia. The protocol enhances the IEEE 802.11 MAC layer.

The 802.11e enhances the DCF and PCF through a new coordination function: the HCF. Within the HCF are two methods of channel access similar to those defined in the legacy 802.11 MAC: HCF controlled channel access (HCCA) and enhanced DCF channel access (EDCA). Both EDCA and HCCA define traffic classes (TCs). For example, e-mails could be assigned to a low-priority class, and VoWIP could be assigned to a high-priority class.

- **EDCA:** High-priority traffic has a better chance of being sent than low priority traffic; a station with high-priority traffic waits a little less time before it sends its packet, on average, than a station with low-priority traffic. In addition, each priority level is assigned a transmit opportunity (TXOP), a window of time that a given station (STA) or AP has to send as many frames as possible. This helps minimize the problem of low-rate stations gaining an inordinate amount of channel time in the legacy 802.11 DCF MAC. WMM-certified APs must be enabled for EDCA and TXOP. All other enhancements of the 802.11e amendment are optional.
- **HCCA:** HCCA is similar to PCF: the interval between two beacon frames is divided into two periods, the CFP and the CP. During the CFP, the hybrid coordinator (HC)—which is also the AP—controls the access to the medium. During the CP, all stations function in EDCA. The main difference with PCF is that TCs are defined; moreover, the HC can coordinate the traffic in any fashion it chooses, not just round robin. Stations provide information about the lengths of their queues for each TC. The HC can use this information to award priority to one station over another. Another difference is that stations are given a TXOP: they may send multiple packets in a row for a given time period selected by the HC. During the CP, the HC allows stations to send data by sending CF-poll frames.

HCCA is generally considered the most advanced (and complex) coordination function. With the HCCA, QoS can be configured with great precision. QoS-enabled stations have the ability to request specific transmission parameters (e.g., data rate, jitter, etc.), which should allow advanced applications like VoIP and video streaming to work more effectively on a WiFi network.

HCCA support is not mandatory for 802.11e APs. In fact, few (if any) APs currently available are enabled for HCCA. The WiFi Alliance has a forthcoming certification (WMM scheduled access) that will allow network integrators to easily distinguish APs that allow HCCA.

Other 802.11e Specifications

In addition to HCCA, EDCA, and TXOP, 802.11e specifies additional optional protocols for enhanced 802.11 MAC layer QoS:

- **Automatic power save delivery (APSD):** A more efficient power management method than legacy 802.11 power save polling. Most newer 802.11 STAs already support a power management mechanism similar to APSD.
- **APSD is very useful for a VoIP phone** because data rates are roughly the same in both directions. Whenever voice data are sent to the access point, the access point is triggered to send the buffered voice data in the other direction. The voice over IP phone then enters a doze state until the next voice data have to be sent to the access point.
- **Block acknowledgements (BAs):** Allow an entire TXOP to be acknowledged in a single frame. This provides lower protocol overheads when longer TXOPs are specified.

- **NoAck:** In QoS mode, service classes for outgoing frames can have two values: QoSAck and QoSNoAck. Frames with QoSNoAck are not acknowledged, which avoids retransmissions of highly time-critical data.
- **Direct link setup (DLS):** Allows direct STA-to-STA frame transfer within a BSS. This is designed for consumer use, where STA-to-STA transfer is more frequent.

Limitations of IEEE 802.11 in Supporting Voice

Recent research has shown that neither DCF nor EDCA is effective or efficient in supporting delay-sensitive voice traffic. Their contention-based natures and binary exponential back-off mechanisms cannot guarantee that a voice packet will be successfully delivered within the required delay bound. In addition, the time to transmit the payload of a voice packet is only a very small portion of the total time to transmit the packet, as a result of overheads such as the RTP/UDP/IP headers, MAC header, and physical (PHY) preamble. Subsequently, the capacity to accommodate voice traffic in DCF or EDCA is very limited. Active research efforts are focusing on enhancing the performance of voice services using IEEE 802.11e (Wang, Jiang, and Zhuang 2006).

CONCLUSION

VoIP is one of the fastest growing Internet applications today. Given the significant cost savings and benefits that can be achieved with VoIP, interest in this technology continues to grow. Many emerging VoIP solutions and products are exploiting packet-switched networks of the Internet to carry voice traffic using IP. This chapter has presented an overview of VoIP technology and some of its recent growth trends, and has discussed fundamental concepts of VoIP as well as the hardware, software, and protocol support required to deploy it. However, several issues still need to be resolved before VoIP becomes truly ubiquitous. One of these issues, which recently has garnered a lot of attention, is VoIP over WLANs. The major obstacles that can degrade VoIP performance over WLANs—and make VoIP unusable because of significant delay, jitter, or packet loss—have been introduced. Innovative techniques need to be investigated that will efficiently support VoIP transmissions over WLANs. Only with the advent of such techniques will a true end-to-end VoIP solution (spanning both wired and wireless networks) become feasible and pave the way for wide deployments of VoIP over both wired and wireless IP-based infrastructures.

ACKNOWLEDGMENT

This work was supported by grants from Sun Microsystems (Palo Alto) (EDUD-7824-000145-US), Microsoft Corporation (Seattle), and Ixia Corporation (Calabasas). We thank the anonymous reviewers for their comments and suggestions, which helped to improve the quality of this chapter. We would also like to thank the following colleagues for their help and support during the preparation of this article: Joe Oravec, Cassandra Daugherty, Mustafa Siddiqui, Scott Fowler, Aarti Kumar, and Zhaoming Zhu. We express our sincere gratitude to the editor-in-chief,

Hossein Bidgoli, for his patience, encouragement, and kind support throughout the preparation of this chapter.

GLOSSARY

Codec: An acronym for coder-decoder. A codec performs conversions between analog voice and the compressed digital representation of the voice. Coding is done at the entry point to a packet network, and decoding is done at the exit point of the packet network.

Compression: The reduction in size of data in order to save space or transmission time.

H.323: A standard approved by the International Telecommunications Union (ITU) in 1996 to promote compatibility in videoconference transmissions over IP networks.

Jitter: In VoIP, the variation in the time between packets arriving; caused by network congestion, timing drift, or route changes.

Latency: A synonym for *delay*; is an expression of how much time it takes for a packet of data to get from one designated point to another. In some cases, latency is measured by sending a packet that is returned to the sender; the round-trip time is considered the latency.

Mean Opinion Score (MOS): In voice communications, particularly Internet telephony, this provides a numerical measure of the quality of human speech at the destination end of the circuit. The scheme uses subjective tests (opinionated scores) that are mathematically averaged to obtain a quantitative indicator of the system performance.

Public Switched Telephone Network (PSTN): The world's collection of interconnected voice-oriented public telephone networks, both commercial and government owned; also referred to as the plain old telephone service (POTS).

Quality of Service (QoS): On the Internet and in other networks, this is the idea that transmission rates, error rates, and other characteristics can be measured, improved, and, to some extent, guaranteed in advance. QoS is of particular concern with regard to the continuous transmission of high-bandwidth video and delay-sensitive multimedia information.

Session Initiation Protocol (SIP): An Internet Engineering Task Force (IETF) standard protocol for initiating an interactive user session that involves multimedia elements such as video, voice, chat, gaming, and virtual reality.

VoIP (Voice over IP): An IP telephony term for a set of facilities used to manage the delivery of voice information over the Internet. VoIP involves sending voice information in digital form in discrete packets rather than using the traditional circuit-committed protocols of the public switched telephone network (PSTN).

VoWLAN (Voice over WLAN): A method for sending voice information in digital form over a wireless broadband network. Essentially, VoWLAN is VoIP delivered via wireless technologies.

Wired Equivalent Privacy (WEP): A security protocol, specified in the IEEE wireless fidelity (WiFi) standard, 802.11b, that is designed to provide a wireless local

area network (WLAN) with a level of security and privacy comparable to what is usually expected of a wired local area network (LAN).

INTRODUCTION

As Internet Protocol (IP) networking evolves to support all kinds of applications, signaling becomes an essential part of networks and applications, providing the means for many functions, including resource management and control, security support, service announcement and initiation, and capabilities negotiation. This chapter addresses the main signaling approaches in use or being proposed for the current, highly heterogeneous Internet. Signaling in the Internet is quite different from the traditional networks, in which a separate path was used for management and signaling. IP-based networks utilize the data, management, and control planes over a single channel.

OBJECTIVES AND ORGANIZATION

The Objectives of Signaling

Signaling can be defined as the exchange of data needed among network elements and end systems to support the setup, maintenance, and release of the network services. In IP based networks, signaling is needed at the application layer, transport, and network levels. At the application layer, signaling is needed to manage application sessions (e.g., VoIP or videoconferencing session) and to negotiate service parameters between the applications. At the transport level, signaling is needed to set up and tear down connections between the end systems, and to perform flow, congestion, error, and synchronization control in the active connections. Signaling also is needed at the network level to support mobility or for dynamic discrimination of

flows (or flow aggregates) to give these flows a treatment different from the normal flows (e.g., different route, priority, delay, or security treatment).

Signaling always has been a controversial issue when the Internet is concerned. Ideally, signaling on the Internet should be reduced to a minimum and should be performed by end-systems, to keep the network as simple as possible. Reality has shown that this is not possible.

Although the current Internet is still data-driven—as opposed to the signaling-driven nature of, for instance, the telephone network—signaling is present in virtually all its components, for network operations support, quality of service support, management, and application/user support.

IP companion protocols such as ICMP (Internet Control Message Protocol), ARP (Address Resolution Protocol) and DHCP (Dynamic Host Configuration Protocol) perform network operation signaling. Routing protocols such as OSPF (Open Shortest Path First) and BGP (Border Gateway Protocol) can carry signaling information used for network signaling operations. RSVP (Resource Reservation Protocol), MPLS (Multi-Protocol Label Switching) signaling extensions and NSIS (Next Steps in Signaling) are examples of signaling protocols that support quality of service and resource control. SNMP (Simple Network Management Protocol) and COPS (Common Open Policy Service) are examples of management protocols.

SIP (Session Initiation Protocol) and H.323 are examples of application/user support signaling protocols. Session and transport protocols such as TCP (Transmission Control Protocol), RTSP (Real Time Streaming Protocol),

and RTCP (Real Time Control Protocol) also include signaling mechanisms for application/user support, to ensure end-to-end connectivity with flow, error, and synchronization control.

All of the above protocols and mechanisms have the common objective of providing some form of control and support of user traffic and communication services. Thus, they contribute to the good operation of the network.

Signaling mechanisms can be on-path or off-path. When signaling messages follow the same path as data messages, it is said that on-path signaling is being performed (also mentioned as path-coupled or in-band signaling). Sometimes, however, entities that are not on the data path have to be signaled. Signaling protocols that allow the signaling of entities that are not on the data path are called off-path signaling protocols (also mentioned as path-decoupled or out-band signaling). Hybrid signaling solutions using on-path signaling inside each domain and off-path signaling between domains also are possible. The EuQoS project signaling approach described later in this chapter is an example of hybrid signaling.

Signaling also can be explicit or implicit. Explicit signaling is achieved through explicit messages that can be carried together with user data, in specific packet fields, as in TCP header fields, or in separate signaling packets, as in RSVP and NSIS. Implicit signaling information can be extracted from the normal application flow to trigger reservation mechanisms in network devices. Some signaling solutions, such as the EuQoS project approach, combine implicit signaling near the end-systems (to reduce the complexity of end-systems) and explicit signaling inside the network.

Signaling is closely related to the amount of state information stored in the network elements. State information can be stored per flow or per flow aggregates. State information can be maintained until explicitly released (hard-state) or expire after a given time limit if not refreshed before (soft-state). If state information is needed per flow, signaling also has to be performed on a per-flow basis; otherwise signaling is needed only to manage the flow aggregates. In soft-state approaches, signaling has to be issued periodically to refresh the state information. In hard-state approaches signaling is needed only for the establishment and release of state information.

The definition of a signaling scheme is a trade-off between the application needs and the complexity introduced in the network. Best effort applications need basic signaling mechanisms for flow, error, and congestion control like the ones included in TCP. Multimedia applications, with quality of service requirements, can operate smoothly if the network is over-provisioned. In a limited resource environment they will require per flow or aggregated signaling to support resource reservation and traffic differentiation mechanisms. Thus, there is also a trade-off between the amount of signaling and network resources.

Overall, the definition of the signaling mechanisms for the support of real-time applications over the global Internet with quality and security is still an open issue. The solution is expected to emerge from the signaling proposals being discussed and standardized at the Internet Engineering Task Force (IETF) and considering the settlement of the above trade-offs.

This chapter describes the main signaling protocols and mechanisms for IP networks. The focus is on signaling protocols for network operation and quality of service support. Signaling mechanisms embedded in routing and transport protocols will be mentioned only briefly because these protocols are covered in specific chapters in this book. For each signaling protocol described, the main advantages, limitations, and deployment trade-offs are discussed.

Organization of the Chapter

The main on-path and off-path signaling protocols for IP networks are presented in this chapter. The first section is dedicated to the Resource Reservation Protocol (RSVP), an important signaling protocol for quality-of-service provision in Integrated Services environments. This protocol has inspired the emerging IETF's Next Steps In Signaling (NSIS) framework, which is addressed in the second section of the chapter. The third section is devoted to the two main signaling protocols for voice, video and multimedia support: SIP and H.323.

Other relevant signaling protocols and approaches are presented later of which Common Open Policy Service (COPS) and Multi-Protocol Label Switching (MPLS) signaling extension are the most important. The chapter ends with a brief presentation of a case study—the EuQoS project—in which various signaling protocols and approaches are combined to provide end-to-end quality of service over heterogeneous networks.

RESOURCE RESERVATION PROTOCOL Background

Resource reservation is a preventive way to provide quality-of-service guarantees. By reserving resources along a given path, the flows are protected from congestion situations and get the contractually agreed service level no matter what the network usage level is. This is good, of course, from the user perspective but may be not as good from the network operator perspective, as resources are reserved and cannot be used by other flows even if the respective flows are not using them.

The Resource Reservation Protocol (RSVP) originally was defined in RFC 2205 (Braden et al. 1997), later updated by RFC 2750 (Herzog 2000), and provides ways to perform resource reservation in Internet-like environments. The basic idea behind RSVP is that receivers identify their quality of service needs and send signaling messages upstream (i.e., toward the sources) that will be used by routers along the path to reserve the necessary resources. RSVP was designed to overcome the limitations of the Internet Stream Protocol Version 2, ST2 (Delgrossi and Berger 1995).

RSVP is the signaling protocol used by the Integrated Services (IntServ) QoS architecture, as specified in RFC 2210 (Wroclawski 1997), for the support of multiple traffic types, including data traffic, audio traffic, and video traffic. In IntServ, resources are reserved at network elements on an individual flow basis, through the use of RSVP. This

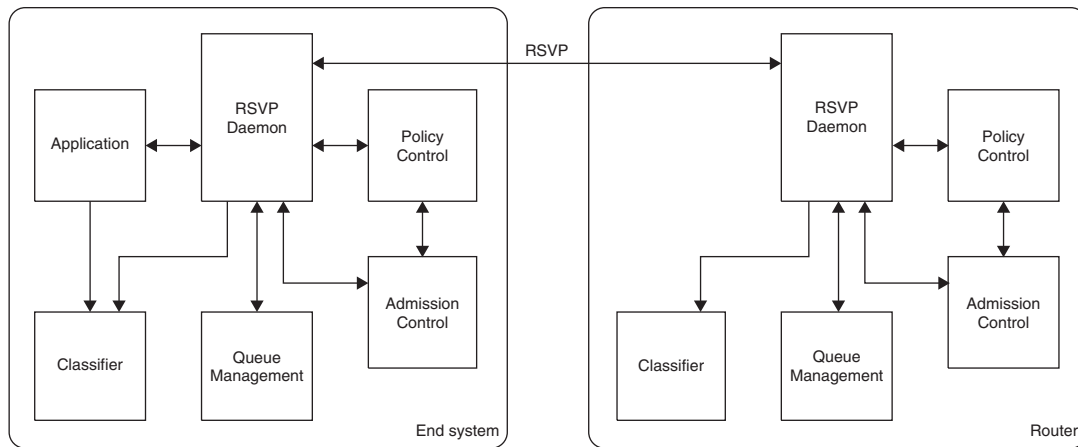

Figure 1: IntServ architecture

approach supports what is called the fine-grained QoS provision, as routers must be aware of the QoS needs of each of the existing flows. With this approach, the IntServ architecture provides three classes of service: best effort (the Internet's default service), controlled load (similar to best effort in an uncongested network), and guaranteed service (assured bandwidth, no losses, and bounded delay service).

In addition to signaling, which is based on RSVP, IntServ requires a set of other supporting functions to provide quality-of-service guarantees—namely, policing, shaping, admission control, packet classification, and queue management. Figure 1 presents the general IntServ architecture.

Although resource reservation has clear advantages in some cases, it is not feasible in a large network or service provider environment because of the high signaling overhead. RSVP messages pertain to individual flows and must be refreshed periodically. This leads to scalability problems and precludes the use of IntServ in core networks, where the number of flows may be extremely high.

Main Characteristics of RSVP

RSVP was designed to support both unicast and multicast operation—meaning that it supports reservations for unicast and multicast flows. Resources are reserved based on the individual requirements of multicast members. In addition, RSVP dynamically adapts itself to changing group membership and to changing routes.

RSVP has a simple mode of operation. Reservations are made for unidirectional data flows. Bidirectional flows require two separate reservations. This is tied to the fact that resource reservations are receiver-initiated, which, in turn, results from the fact that different members (receivers) of a multicast group may have different QoS requirements and, thus, may require dissimilar resources.

Another important characteristic of RSVP is that it is a soft-state protocol. IP is a stateless, connectionless-oriented protocol. Thus, one of the major concerns of the RSVP developers was to avoid connection-oriented operation. The way to do this was to cause reservations (i.e.,

state kept in the routers) to expire unless receivers were to regularly refresh them. This has some drawbacks and some advantages. On one hand, it leads to higher communication overhead, as reservation messages continue to be generated and sent over the network. On the other hand, if a receiver leaves a multicast group or if a route changes, the reservations for the unused route expire, without the need for any further action.

A key aspect of RSVP is the aggregation of reservation requests. As reservation requests flow from receivers to sources, routers along the way can aggregate resource requests (e.g., bandwidth requests) whenever possible, thereby optimizing the use of Internet resources. There are several forms of aggregating reservation requests for the same multicast group, depending on the reservation style used by the receivers. This will be explained later in this chapter. Figure 2 illustrates the aggregation of reservation requests for a given multicast group. In this figure, requests from Hosts 1 and 2 are merged at Router 3. This merged reservation request, in turn, is merged with that from Host 3 at Router 1.

RSVP Data Flows

RSVP data flows are called sessions. A session is characterized by the session identification, a flow specification, and a filter specification. The session identification is composed of the destination IP address (unicast or multicast), the IP user-protocol identifier (e.g., TCP, UDP), and the destination port. The flow specification, FlowSpec, determines the desired quality of service and is composed of the following sub-parameters: Service class, which identifies the requested type of service; Reservation specification, Rspec, which defines the desired QoS; and Traffic specification, Tspec, which describes the data flow. The filter specification, FilterSpec, determines the packets the reservation applies to. The FilterSpec parameters consist of the source address and/or the TCP/UDP source port.

Figure 3 illustrates the handling of packets in a session. First the FilterSpec is checked. On the one hand, the packets that do not pass the filter get a best-effort service. On the other hand, the packets that pass the filter specification get the service determined by the flow specification.

Figure 2: Aggregation of reservation requests

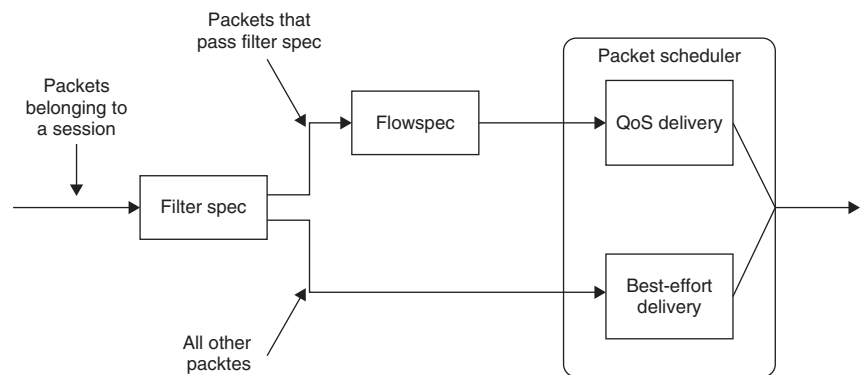

Figure 3: Handling of packets in an RSVP session

RSVP Protocol Operation

The RSVP protocol relies on two basic message types: RESV and PATH. RESV messages are originated by unicast or multicast group receivers requesting resource reservation for packet flows from one or more sources. These messages propagate upstream through the distribution tree, and the respective resource requests can be merged when appropriate at each node (router) along the way. RESV messages create soft states within the routers of the distribution tree, and they must be reissued periodically to maintain the resource reservation.

PATH messages are generated by sources to announce themselves as multicast group sources. These messages are transmitted downstream through the distribution tree to all multicast destinations. Each router along the way creates a path state that indicates the reverse hop to be used for the corresponding source. Similarly, each destination host creates a path state that indicates the reverse hop to be used for the corresponding source. This path state allows hosts and routers to route RESV messages.

The RSVP signaling protocol basic operation sequence can be described as follows:

1. A receiver joins a multicast group, by using the general group management mechanism, i.e., by sending

an IGMP Join message to a multicast router in its network.

2. A source issues a PATH message to the multicast group.
3. The receiver receives the PATH message identifying the source.
4. The receiver uses the reverse path information to send RESV messages, specifying the desired QoS.
5. The RESV message propagates upstream, is merged with other RESV messages from other receivers, and is delivered to the source.
6. The source starts sending data packets.
7. The receiver starts receiving data packets.

This basic operation is illustrated in Figure 4.

Other RSVP messages include: teardown, error, and confirmation messages. Teardown messages remove the path and reservation state without waiting for the cleanup timeout period. These messages can be generated by a receiver, or an intermediate router as the result of a state timeout. Reservation-request teardown messages delete the reservation state, travel upstream toward all senders from the point of teardown initiation, and are routed like reservation-request messages. To add reliability to the requests, RSVP

Figure 4: RSVP protocol operation sequence

Table 1: RSVP reservation styles

	Distinct Reservation Attribute	Shared Reservation Attribute
Explicit Sender Selection	Fixed-Filter (FF)	Shared-Explicit (SE)
Wild-card Sender Selection	---	Wild-card Filter (WF)

contains three error and confirmation messages: path-error messages, reservation-request error messages, and reservation-request acknowledgment messages.

Reservation Styles

Reservation styles determine the way in which resource requirements are aggregated at each router. The three reservation styles are determined by a combination of two options: the reservation attribute and the sender selection. The former can specify a distinct reservation for each sender or, alternatively, a shared reservation applicable to groups of senders. The latter can specify an explicit list of sources or all sources (wild-card). The combinations that lead to the three reservation styles—wild-card filter (WF), shared-explicit (SE) filter, and fixed filter (FF)—are identified in Table 1.

In the wild-card filter reservation style, reservations are made irrespective of the senders and, thus, are applicable to all senders of the group. This is the simplest reservation style, and the one with more potential in terms of request aggregation, as any resource request is valid to all senders of the group. A wild-card filter reservation style scenario

is illustrated in Figure 5. In this figure, bandwidth reservation is requested by the sources in multiples of B bandwidth units. For each link, the router simply propagates upstream the highest bandwidth request received from the downstream links.

In the shared-explicit filter reservation style, receivers provide an explicit list of sources, but the reservations may be shared by several sources. This scenario is illustrated in Figure 6.

In the case of the fixed-filter reservation style, receivers perform a distinct reservation for each sender and, thus, requests can be aggregated at routers only if they pertain to the same source. This scenario is illustrated in Figure 7.

RSVP Traffic Engineering Extensions

RSVP was extended to establish Label-Switched Paths (LSPs) in MPLS (Multi-Protocol Label Switching). These extensions, called RSVP-TE extensions, enable the creation of MPLS Traffic Engineering (TE) tunnels to handle specific traffic aggregates. Tunnels can be created automatically to circumvent network failures, congestion, and bottlenecks.

Figure 5: Wild-card filter reservation style

Figure 6: Shared-explicit filter reservation style

Figure 7: Fixed-filter reservation style

Operation of RSVP-TE with MPLS is described below, together with the description of the MPLS signaling extensions.

RSVP Security Mechanisms

RSVP includes mechanisms for information integrity and authentication. Confidentiality, however is not supported by RSVP. The security operation is supported by establishing security associations between RSVP entities and by the exchange of AUTH_DATA and INTEGRITY objects.

The AUTH_DATA object is used to authenticate RSVP PATH or RESV messages. The INTEGRITY object is used to provide integrity and authentication of the content of the signaling message exchange between two RSVP entities (two routers or a router and a host).

The Integrity Handshake protocol allows an RSVP entity to recover, after a failure, the sequence numbers used for reply attack protection.

RSVP security properties are summarized in RFC 4230 (Tschofenig et al. 2005).

NEXT STEPS IN SIGNALING

Background

Next Steps In Signaling (NSIS) is a signaling framework being developed by the Internet Engineering Task Force (IETF) in the context of the NSIS Working Group (Hancock et al. 2005) for the purpose of installing and maintaining flow states in the network. NSIS is based on various signaling protocols, the main one being RSVP. The intention is to reuse RSVP mechanisms whenever possible, because these mechanisms already have been widely tested, leaving out all unnecessary complexity (e.g., multicast support). Thus, it is a simpler and more scalable approach to resource reservation, when compared to RSVP.

By using a two-layer signaling architecture, signaling transport is separated from signaling applications.

This architecture opens the way to develop several emerging signaling applications, of which quality of service signaling is the first-use case to be implemented.

Initial requirements of NSIS include support for the independence of application signaling and network control mechanisms, ability to place NSIS initiators, forwarders, and responders anywhere in the network through on-path and off-path signaling, transparent signaling through the network (the signaling message are opaque for the signaling transport), grouping of signaling for several micro-flows, flow aggregation, scalability, flexibility, and security.

NSIS Characteristics

Although NSIS can work on a per-flow basis, it allows flow aggregation based on the use of the DSCP field or tunnels. In addition, it works on a hop-by-hop basis, between NSIS-aware nodes (NSIS Entities, NE, also referred to as NSIS hops). Nodes not supporting NSIS are transparent, which means that there is no need for deployment of NSIS in every network entity. This is illustrated in Figure 8, where the end-systems and two of the routers support NSIS Entities that exchange signaling messages related to the data flow.

NSIS allows signaling to hosts, network elements, and proxies. Proxies allow the existence of NSIS-unaware hosts, by carrying out signaling on their behalf, as illustrated in Figure 9.

As stated before, NSIS supports both on-path and off-path signaling. In the case of path-coupled signaling, signaling messages are routed through NSIS entities on the data path only, although between adjacent NEs, the route taken by signaling and data might diverge. In the case of path-decoupled signaling, messages are routed to NEs, which are not assumed to be on the data path but which are aware of it (NEs have to know the path topology). In this case, the signaling endpoints may have no relation at all to the ultimate data sender or receiver.

Figure 8: Simple NSIS scenario

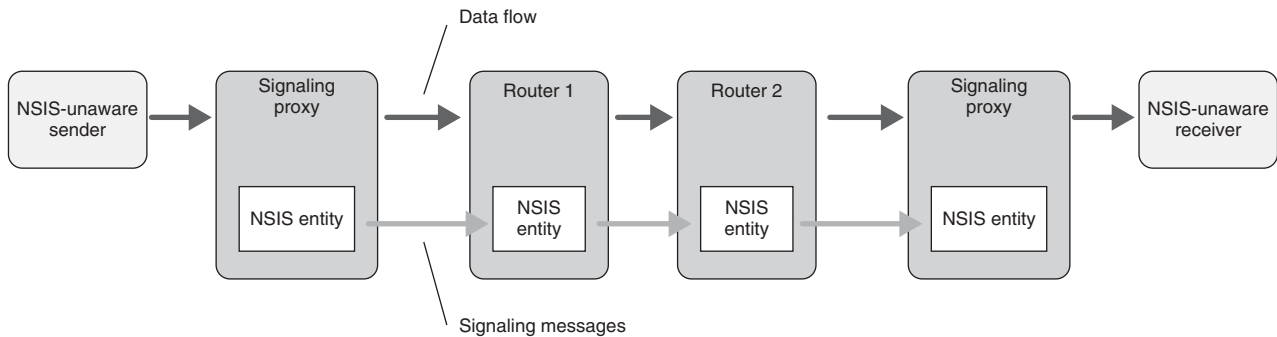

Figure 9: Signaling proxies

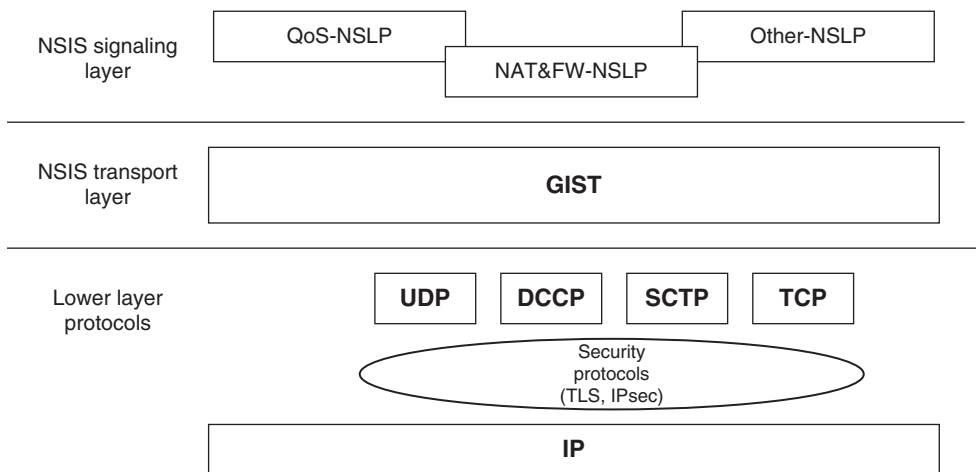

Figure 10: NSIS two-layer architecture

NSIS Architecture

NSIS is being developed as a two-layer modular architecture, comprising an NSIS transport layer and an NSIS signaling layer. The NSIS transport layer protocol, known as General Internet Signaling Transport (GIST), is responsible for the transport of signaling messages between network entities. The signaling layer contains specific functionality of signaling applications and may have several NSIS signaling layer protocols, generically known as NSLPs. With this approach, illustrated in Figure 10, the transport of the signaling messages and the signaling application are separate, which allows the use of the same signaling transport protocol for the support of all signaling

applications. Examples of signaling protocols are the QoS-NSLP (Manner and Fu 2005) and the Network Address Translation (NAT) and Firewall (FW) NSLP (Stiernerling et al. 2006).

GIST

The GIST layer is responsible for the transport of signaling messages. When a signaling message is ready to be sent, it is passed to the GIST layer along with flow information details associated with it. Then it is up to the GIST layer to get the message to the next NSIS Entity (NE) along the path, downstream in the flow direction from the source to

Figure 11: Example of GIST transport between NSIS entities

the destination, or upstream in the direction opposite to the flow, from the destination to the source. In the receiving NE, GIST either forwards the message directly to the next hop or, if there is an appropriate signaling application, passes it upward for further processing. The signaling application then can generate another message to be sent via GIST. Figure 11 illustrates this behavior, showing two different signaling applications and how NEs handle the signaling messages accordingly.

GIST allows two modes of operation, Datagram mode (D-mode) and Connection mode (C-mode). D-mode uses UDP to encapsulate messages and is used for small and infrequent messages. The C-mode uses TCP or any other stream or message-oriented transport protocol (currently only Stream Control Transmission Protocol, SCTP, is being considered in addition to TCP), which allows GIST to provide reliability and security (for example, using Transport Layer Security, TLS, over TCP) in the message transport. In addition, GIST defines a three-way handshake connection setup between adjacent peers, composed of a Query, a Response, and an optional Confirm message.

GIST was designed as a soft-state protocol to manage all the messages and associations. Each time a state is entered or updated, a timer is set up or restarted. GIST has two main state tables: Message Routing State (MRS) and Message Association State (MAS). The MRS is responsible for managing individual flows and the MAS is responsible for managing associations between individual peers. When a timer expires (if no message is received for the corresponding flow or association), the state is automatically removed from the state tables. If a state is required again, a new handshake is needed and a new association must be created.

QoS-NSLP

To be able to establish and maintain resource reservations, QoS-NSLP (Karagiannis and McDonald 2006) defines four message types: RESERVE, QUERY, RESPONSE, and NOTIFY. Each message contains three parts: Control information, QoS specification (QSPEC), and Policy objects.

The RESERVE message is used to create, refresh, modify and remove states. RESERVE messages are the only messages that manipulate states, and if received more than once, the result is the same. The QUERY message is used to probe the network without installing or changing any state. The result of a QUERY message can be used to configure subsequent messages. The RESPONSE message is used to provide feedback from previous messages. The NOTIFY message is similar to the RESPONSE message but is an asynchronous message that can be generated without any previous message. Usually the NOTIFY messages report error conditions.

Figure 12 illustrates the use of QoS-NSLP in a basic reservation scenario. The figure shows the signaling messages exchanged with time (time elapses from the top to bottom). This example represents a receiver-initiated reservation, in which the data sender probes the network by means of a QUERY message that gathers information on the network capability. When this message arrives at the receiver, it triggers the start of the reservation. The receiver, which in this case plays the role of QoS NSLP Initiation, QNI, starts the reservation by sending a RESERVE message to the QoS NSLP Responder, QNR. This message will install the request in the network. In all NSIS entities along the data path for which the QoS NSLP is available, the message is processed (in this case in the two QNEs) and the reservations are made if possible. After the request is installed

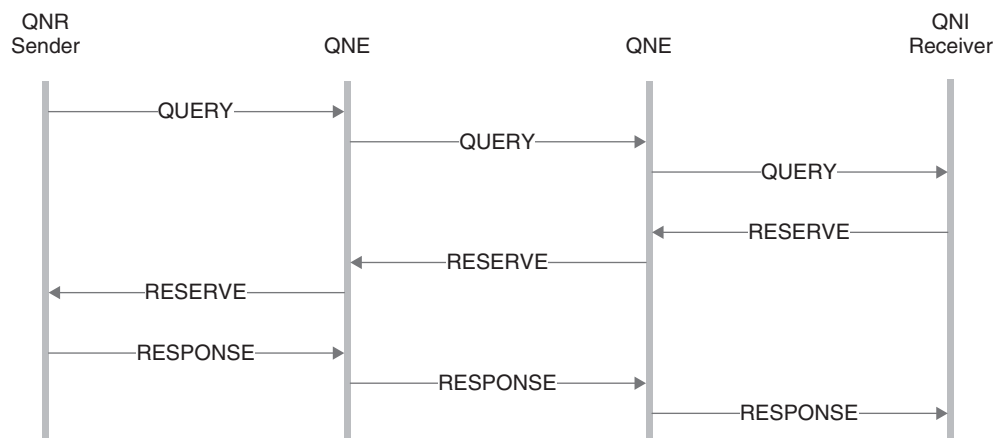

Figure 12: QoS NSLP basic reservation scenario

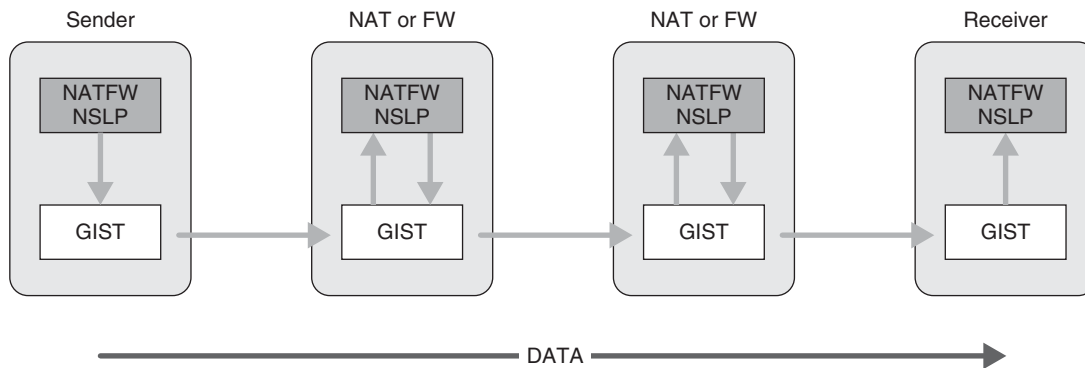

Figure 13: NATFW NSLP scenario

in the QNR, the QoS-NSLP generates a RESPONSE message. This message is sent to the QNI along with the result of the RESERVE message. When this message arrives at the QNI, the procedure is complete.

NAT and Firewall NSLP

The NAT and Firewall (NATFW) NSIS Signaling Layer Protocol (Stiemerling et al. 2006) is being defined in the NSIS IETF Working Group to provide dynamic configuration of NAT and firewall devices along the data path of a specific flow. These types of devices may create obstacles to applications such as IP telephony and peer-to-peer application unless appropriate firewall rules or NAT bindings are in place.

Figure 13 illustrates a simple example of NATFW NSLP use between a sender and a receiver, with two middleboxes network elements (NAT or firewall devices). The source host (sender) generates a NATFW NSLP signaling message and sends it to the destination host (receiver). This message traverses the data path, and hence every NSIS entity having NATFW NSLP functionality will process it. Based on the message-processing outcome, the NATFW NSLP triggers configuration changes of the middleboxes network elements accordingly and forwards the message to the receiver. Middleboxes are configured for the specific flow and the data flow can start.

NATFW NSLP signaling messages contain general information (such as IP address, ports, protocol) and policy rules. Policy rules are abstractions of actual network equipment policy rules. The request initiator generates the abstract policy rules, and in each NATFW NSLP along the path, these rules must be mapped to the specific NAT or firewall rules. This mapping is vendor- and model-dependent.

NATFW NSLP defines five message types: CREATE, RESERVE-EXTERNALADDRESS(REA), TRACE, NOTIFY, and RESPONSE. The CREATE message creates, changes, refreshes and deletes NATFW NSLP sessions on the data path between the sender and the destination. The REA message is forwarded from the receiver to the edge NAT to allow inbound CREATE messages to be forwarded to the receiver. This message reserves an external address (and a port number if needed) in the edge router and requests the configuration of all intermediate middleboxes (between the receiver and the edge NAT). The TRACE message gathers

information from all NATFW NSLP on the data path. The NOTIFY message is an asynchronous message used by NSLP to notify upstream peers of specific events. The RESPONSE message is a response to CREATE, REA, and TRACE messages.

NSIS Security Mechanisms

The security mechanisms of the NSIS framework are supported by the Generic Internet Signaling Transport (GIST) protocol that provides the basic signaling transport services to the application signaling protocols. GIST can use available security mechanisms (alone or combined) to ensure authentication, integrity, and confidentiality, namely: Transport Layer Security (TLS) with X.509 PKI; Extensible Authentication Protocol (EAP); and 3GPP (3rd Generation Partnership Project) Generic Bootstrapping Architecture (GBA).

TLS and X.509 PKI certificates can be used to protect GIST message exchange over TCP connections.

EAP used in AAA (Authentication, Authorization, and Accounting) infrastructure can also be used for authenticating of NSIS messages.

The 3GPP GBA key distribution mechanisms can also be used for authorization between NEs.

The discussion about NSIS security mechanisms is ongoing. The Internet-Draft draft-tschofenig-nsis-gist-security-01.txt (Tschofenig and Eronen 2006) summarizes the proposals currently being discussed.

SIP AND H.323

With the advent of multimedia and QoS-demanding applications, the need for application signaling in the Internet became imperative. Applications requiring QoS guarantees include: IP telephony, videoconferencing, multimedia conferencing, and GRID computing.

The two basic types of approaches to application signaling are: data-driven and signaling-driven. The former is the approach typically used on the Internet. The latter has its origin in the traditional telecommunications networks, for which separate signaling and data networks were common. With the convergence of the Internet and the telecommunication communities, both types of approaches can be found in current IP networks.

This section presents the two main application signaling approaches used nowadays: SIP, an Internet-originated approach to application signaling; and H.323, a telecommunications-originated approach. Other application signaling protocols, such as MGCP or MEGACO, will not be addressed, as they are historic only or their installed base is rapidly decreasing in favor of SIP.

Session Initiation Protocol

This subsection is dedicated to the Session Initiation Protocol (SIP), covering the origin, objectives, elements, addressing, message types, and dialogue organization of SIP.

Origin and Objectives

SIP is a text-based application layer control protocol developed by the IETF. It is based on HTTP and, thus, it inherited the message header format from RFC 822 (Crocker 1982). SIP is defined in several RFCs, of which RFC 3261 (Rosenberg et al. 2002) contains the core specification.

SIP is used for multimedia session control—namely, session creation, session modification, and session termination. SIP sessions consist of sets of senders, receivers, and associated states. Telephone calls, multimedia conferences, and distributed computer games are examples of SIP sessions.

SIP provides the mechanisms for establishing point-to-point and point-to-multipoint calls, caller and called authentication, call forwarding and transfer, call forking, terminal capability negotiation, and location-independent addressing.

By itself, SIP is not enough to make the communication possible. It requires some companion protocols—namely, the Session Description Protocol, SDP (Handley and Jacobson 1998) and the Real-Time Protocol Real-Time

Control Protocol, RTP/RTCP (Schulzrinne et al. 2003). SDP is necessary for the description of multimedia sessions (e.g., media types, time characteristics), while RTP/RTCP carries the real-time multimedia data over the network.

SIP Elements

SIP relies on the use of several different types of elements—namely, user agents, proxies, registrars, and redirect servers. Some of these may be logical entities residing in the same system.

User agents (UA) are session endpoints. They negotiate session characteristics and are logically divided into User Agent Clients (UAC), which send requests and receive responses, and User Agent Servers (UAS), which receive requests and send responses.

Proxy servers route session invitations according to the current location of the called party. In addition, they perform user authentication and accounting. Session invitations may traverse several proxies until they reach the remote UA. Proxy servers may be stateless or stateful. The former are simple message forwarders, do not take care of transactions (messages are usually organized into transactions), are faster than stateful proxies, and do not perform forking (for multiparty communication). The latter keep track of ongoing transactions, may perform forking, keep track of retransmissions and can perform call redirection.

Figure 14 illustrates a session establishment between two users from different organizations. Each organization may have its own proxy server. These proxy servers are used to route the session invitation (unless the organizations use hosted service providers).

Registrars usually are co-located with proxy servers. They receive registrations from users and keep track of their current location (namely username, IP address, and port number). User location information is stored in a

Figure 14: Example of SIP session establishment

location database. Because user registrations have a limited life span, user agents must refresh their registration periodically. If a registration is not refreshed, it expires and the user becomes unavailable.

Redirect servers are also usually co-located with proxy servers. They receive location requests and return a list of the current locations of users.

Addresses

SIP entities are identified through Uniform Resource Identifiers (URI), which are similar to e-mail addresses. A SIP URI consists of a username part and a domain part, with the following format: sip:username@domain. This is convenient, as it is thus possible to use the same URI for e-mail and SIP communication, and to use the omnipresent DNS service to find the network location of SIP users and corresponding servers. A SIP URI includes a user phone number and a user IP address or a user Web address.

Although SIP addressing works well on the Internet, it is being adapted to other environments, such as the telephone network. With the advent of IP telephony, for which SIP is being used widely as signaling protocol, it is extremely important to find a way to map traditional telephone numbers (unique numerical addresses administered by the International Telecommunications Union (ITU-T) according to Recommendation E.164) into DNS query strings and, consequently, into SIP addresses. This mapping is provided by ENUM (Electronic Numbering), defined in RFC 3761 (Faltstrom and Mealling 2004).

Messages

The two types of SIP messages are requests and responses. Requests are used to initiate actions. The main types of requests are: INVITE, ACK, OPTIONS, BYE, CANCEL, and REGISTER. Responses, also named replies, are used to confirm that a request has been received and processed. These include a status code that conveys the result of the corresponding request processing. All requests must be replied to, with the exception of the ACK request.

The INVITE message is the first message the calling party sends in the call establishment cycle. It contains endpoint

IDs and call ID, among other parameters. The ACK message indicates that the calling party has received confirmation (a 200 OK response) to an INVITE request. The OPTIONS message is sent to query the capabilities of a call agent—namely, to determine which media types a remote user supports. The BYE message is used to release a call. The sending endpoint terminates the media flow and considers the call terminated. The CANCEL message cancels a request in progress but has no effect if no requests are in progress. The REGISTER message is used by a user agent to register with a local server on start-up. This message is sent to the well-known “all SIP servers” multicast address 224.0.1.75.

Responses convey a status code, suitable to be processed by machines, and a reason phrase, that is, a human-readable message. Both of them describe the result of the processing of the associated request. The SIP responses for defined status code ranges are identified in Table 2.

Transactions, Dialogues, and Calls

SIP messages normally are arranged into transactions, dialogues, and calls. A transaction is a sequence of one request message and all subsequent responses to that request. A request may have zero or more provisional responses and one or more final responses. A dialogue is a sequence of transactions that are related somehow and that persist for some time. Dialogues facilitate the sequencing of messages and can be viewed as peer-to-peer SIP relationships between two user agents. By contrast, a call consists of one or more dialogues and may involve multiple user agents. Each responding user agent establishes a separate dialogue with the calling party.

Figure 15 illustrates a SIP dialogue between two user agents and the constituent transactions.

Figure 16 shows a SIP messages exchange between a calling party and a called party, through a proxy server, for the purpose of establishing a session. The figure illustrates the use of two types of requests (INVITE and ACK) and of provisional responses (100 Trying and 180 Ringing), as well as the positive final response 200 OK. After establishing the session, RTP carries the data streams.

Table 2: SIP Responses

Status code	Description
1xx	Informational (code range 100-199). Proceeding with the execution of the request
2xx	Success (code 200). The request was successfully parsed and executed by the called party
3xx	Redirection (code range 300-399). The call needs more processing by the calling party in order to be completed
4xx	Client request failure (code range 400-499). The request cannot be parsed by the server or cannot be serviced
5xx	Server failures (code range 500-599). The server cannot execute the request
6xx	Global failures (code range 600-699). The user request cannot be serviced by any server

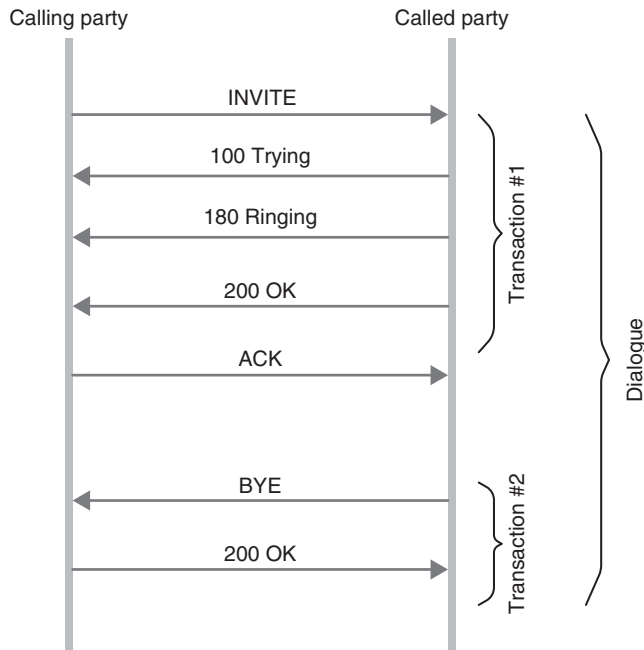

Figure 15: SIP dialogue

SIP Security Mechanisms

As with NSIS, SIP reuses common security protocols to provide security, namely: IP Security protocol (IPSec) and Transport Layer Security (TLS) security with X.509 certificates. TLS security and X.509 certificates of a public key infrastructure (PKI) are used for authentication, integrity, and confidentiality signaling transactions carried by HTTP. IPSec can be used to complement TLS security and provide protection for specific ports and sensitive applications.

RFC 3329 (Arkko et al. 2003) describes the use of TLS and IPSec to provide security to SIP signaling functions.

H.323

This sub-section introduces the ITU-T Recommendation H.323 (ITU-T H.323, 2003), by identifying its origin and objectives, components, protocol architecture, signaling models, and communication phases.

Origin and Objectives

ITU-T Recommendation H.323 is part of a series of recommendations on video telephony and multimedia conferencing services. The first versions of these recommendations were developed in the mid-1990s, addressing the support of the referred services over a variety of network technologies—namely ISDN (H.320), ATM (H.310, H.321), PSTN (H.324), Isochronous Ethernet (H.323), and LANs (H.323).

With the widespread use of LANs, IP protocols, and the Internet in general, the developers quickly arrived at the conclusion that the original H.323 recommendation scope could be extended to Internet-wide deployment, not just LANs. Nowadays, H.323 plays an important role as an application signaling technology, with a large installed base. Nevertheless, because of its complexity and overhead, it is being precluded in favor of SIP. This also is related to the fact that H.323 uses a signaling paradigm that is highly similar to the one used in the telephone network (which is consistent with the fact that it originated in the telecommunications community), as opposed to SIP, which originated in the Internet community.

Components

Figure 17 illustrates the basic components of H.323: terminals, gateways, gatekeepers, and multipoint control units.

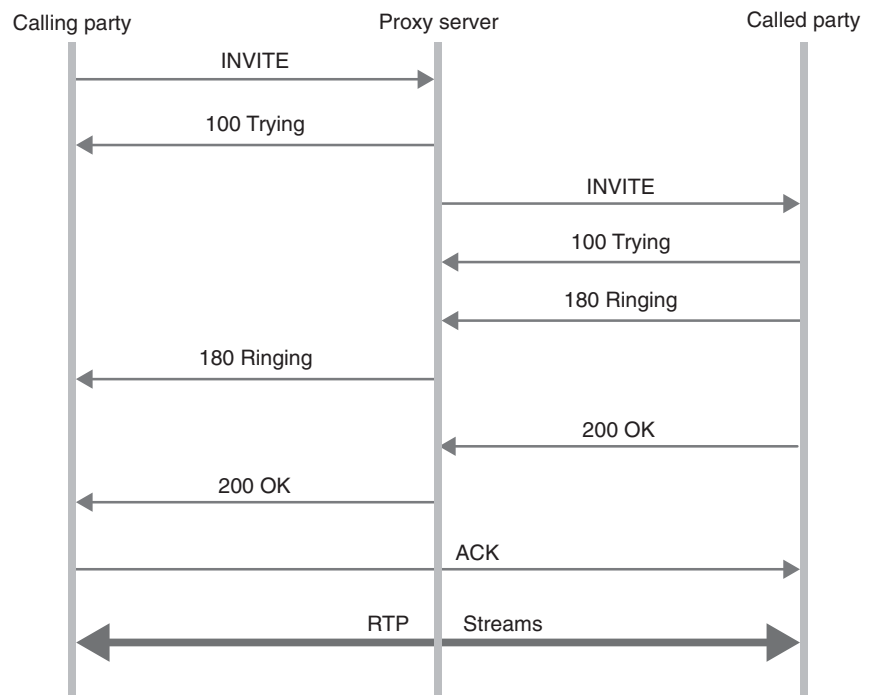

Figure 16: SIP invitation example

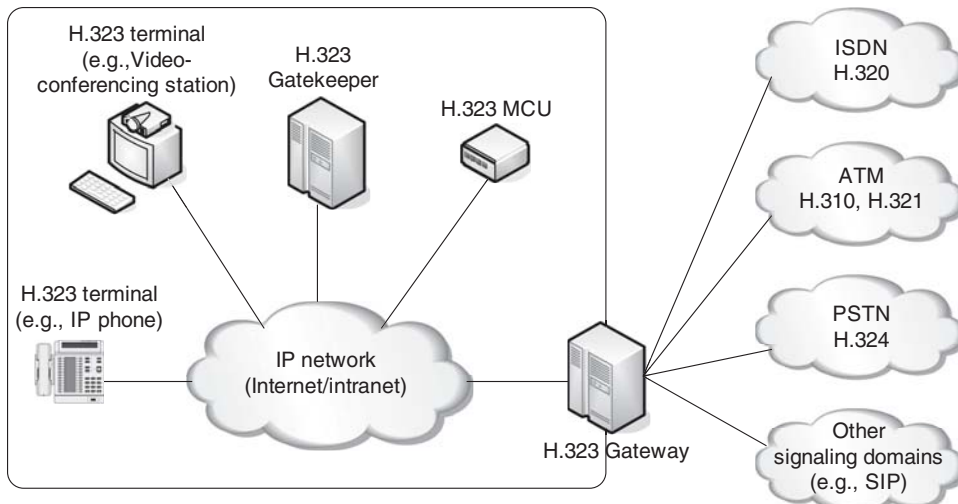

Figure 17: H.323 components

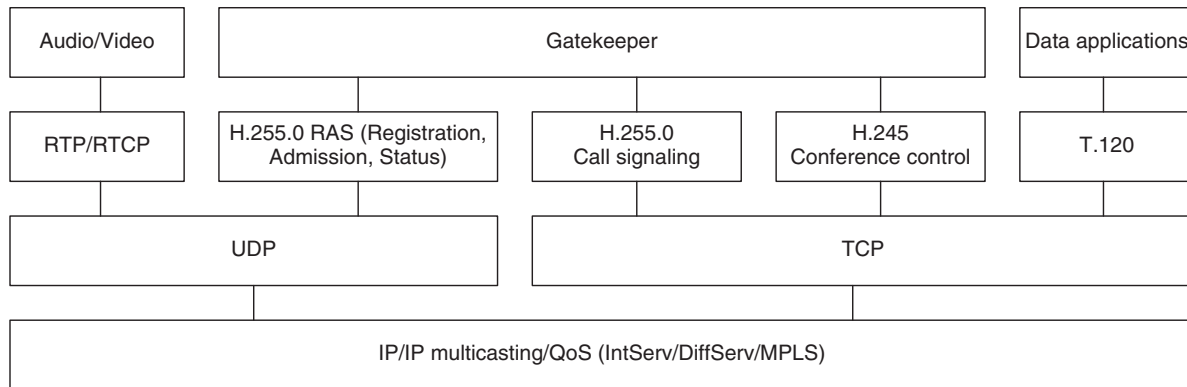

Figure 18: H.323 protocol architecture

Terminals are H.323-capable endpoints, implemented in software or hardware, and with one or more identifiers (URI and/or telephone number). Gateways interconnect H.323 entities with other network and/or protocol environments. Gatekeepers are central management entities of zones. They perform access control, address resolution, call management, and provide basic and supplementary services. They can also act as proxies for security, QoS, or accounting purposes. Thus, in terms of functionality, H.323 gatekeepers are equivalent to SIP proxies. Multipoint Control Units (MCUs) perform multipoint control, i.e., call signaling and conference control of two or more H.323 entities belonging to the same call, and multipoint processing, such as the combination of media streams from individual endpoints belonging to a multipoint call.

Protocol Architecture

H.323 specifies a complex protocol architecture, represented in Figure 18. This includes signaling protocols, data transport protocols, and audio/video transport protocols.

The H.225.0 RAS (Registration, Admission, Status) protocol is used for gatekeeper discovery by endpoints, endpoint registration, endpoint location, endpoint admission requests (authentication/authorization), bandwidth

requests, information on the state of endpoints, and resource availability checks.

The H.225.0 Call Signaling protocol was derived from ISDN call signaling and, in fact, is a simplified version of the Q.931 protocol. It is used for conveying information on call setup intention, call setup progress, call setup success, call setup failure, call release, and call status.

H.245 is used for conference control—namely, for the establishment and control of two-party calls and multi-party conferences, negotiation of modes for media exchange according to terminal capabilities, and configuration of media streams. It is a complex, heavy-weight protocol inherited from other network technologies—namely ATM and the PSTN.

Signaling Models

As mentioned before, H.323 is a complex protocol. The complexity derives from its extensive functionality and modes of operation. The richness of H.323 also is apparent in the signaling models that it uses. These are:

1. *Direct signaling.* In this case, only H.225.0 RAS messages are routed through the gatekeeper. Other signaling messages are exchanged directly between the two endpoints.

Figure 19 (a): Direct signaling

2. *Gatekeeper-routed call signaling.* In this case, H.225.0 RAS and H.225.0 call signaling messages are routed through the gatekeeper. H.245 conference control messages are exchanged directly between the two endpoints.
3. *Gatekeeper-routed H.245 control, RAS, and call signaling.* All signaling messages are routed through the gatekeeper. Only media streams are exchanged directly between the two endpoints.

Figures 19 (a), (b), and (c) illustrate the three H.323 signaling models described above.

Examples of Call Setup

Some H.323 call setup examples follow. Call setup is only the first phase of the several phases in H.323 calls. The various phases are:

1. *Call setup.* Establishment of point-to-point or multipoint calls between parties.
2. *Initial communication and capability exchange.* Role determination (master, slave); terminal capabilities determination.
3. *Establishment of audiovisual communication.* Opening of logical channels for the various information streams.
4. *Call services.* Request/establishment of additional services (e.g., bandwidth changes).
5. *Call termination.*

Figure 20 illustrates a call setup according to the direct signaling model.

Figure 21 illustrates a call setup, now according to the gatekeeper-routed call signaling model.

In addition to the basic services, such as call establishment and termination, H.323 includes several other services, such as multipoint tightly-coupled conferences for which access control and synchronization are performed by an MCU, broadcast loosely coupled conferencing (Mbone style), and supplementary services such as call transfer, call diversion, call hold, and message waiting indication, among other services.

OTHER SIGNALING PROTOCOLS AND APPROACHES

YESSIR and Boomerang

YESSIR (Pan and Schulzrinne 1998) and Boomerang (Manner and Fu 2005) were designed as an attempt to simplify RSVP. YESSIR is an extension to the Real Time Transport Control Protocol, RTCP (Schulzrinne et al. 2003), which reduces the processing overhead to a minimum, uses soft state to maintain reservation states, supports shared reservations, and is able to merge different flow reservations. Boomerang has only one type of message and a single signaling loop for reservation setup and teardown, and it has no requirements on the far-end node. The flow initiator is responsible for all of the protocol management. This protocol supports sender- and receiver-initiated requests.

None of these on-path signaling protocols registered a significant deployment base because of their limitations. Being an extension of RTCP, YESSIR requires support from applications, and routers have to unpack packets

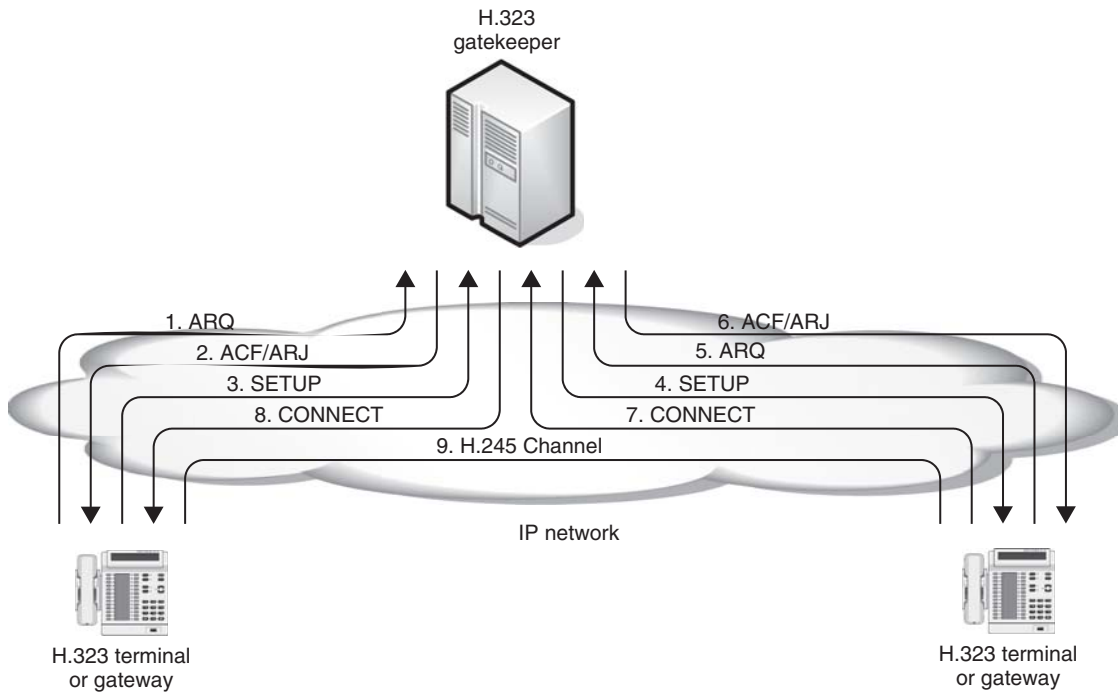

Figure 19(b): Gatekeeper-routed call signaling

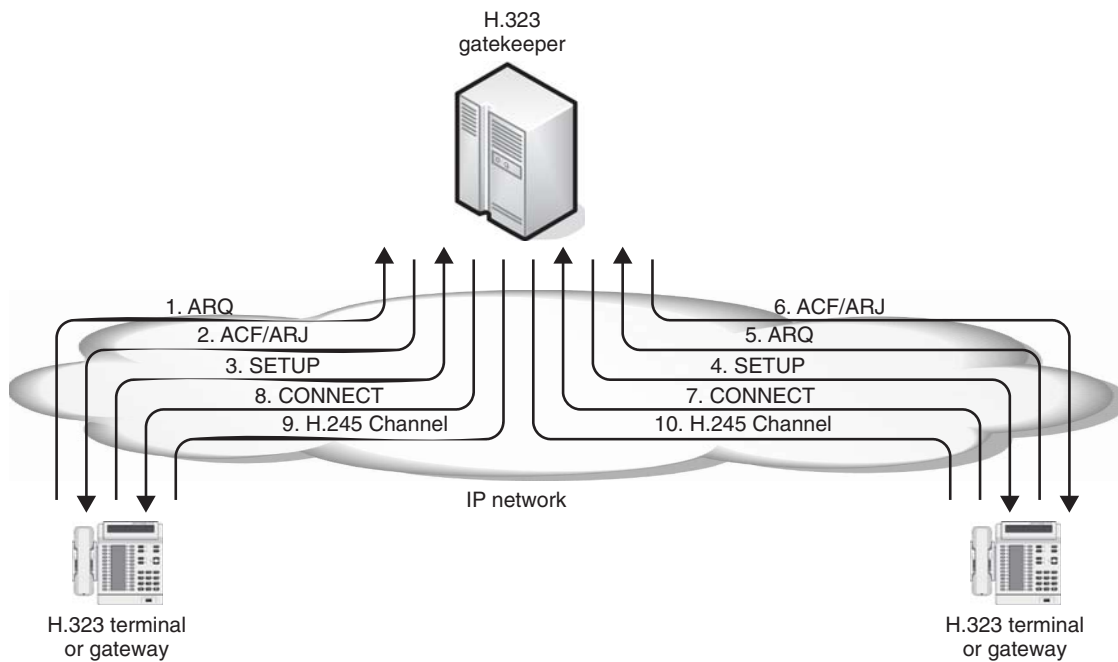

Figure 19(c): Gatekeeper-routed H.245 control, RAS, and call signaling

and analyze the RTCP data. Boomerang is so light that it misses important functionality such as security and multicast.

SIBBS

The Simple Inter-domain Bandwidth Broker Protocol, SIBBS, was defined by the QBone Signaling Design Team, available at <http://qbone.internet2.edu/bb/> (date of

access: January 2, 2007), for use in DiffServ bandwidth-broker-based domains. SIBBS is a simple protocol to be used between Bandwidth Brokers (BB) for resource negotiation between different domains, which uses TCP for reliability. It is composed of two main protocol data units (PDU): Resource Allocation Request (RAR) and Resource Allocation Answer (RAA).

The RAR message includes a globally well-known service identifier, information related to the QoS request

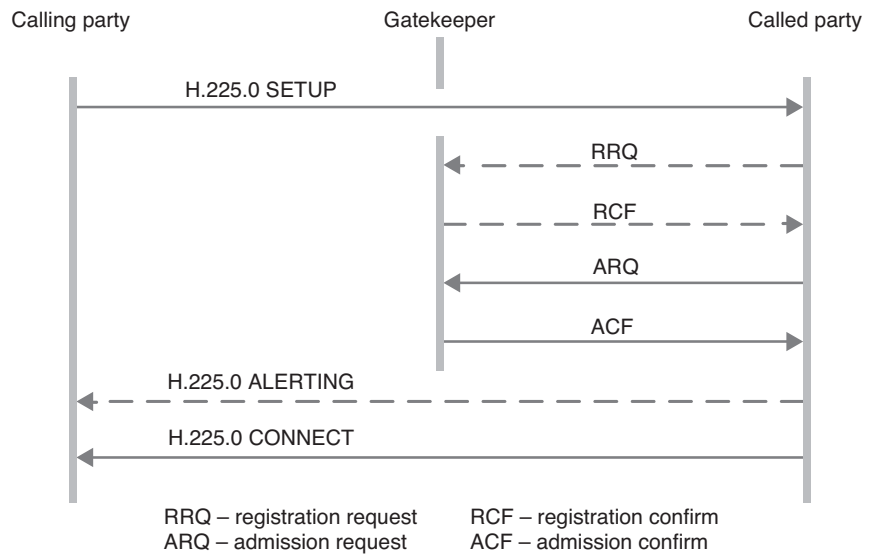

Figure 20: Call setup using the direct signaling model

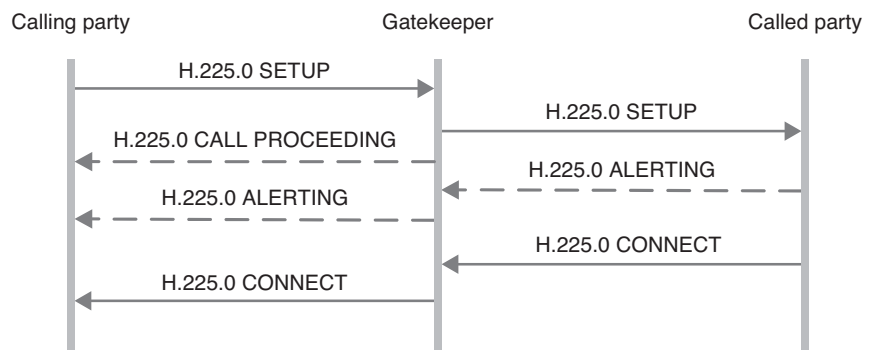

Figure 21: Call setup using the gatekeeper-routed call signaling model

(classes of service and bandwidth), a destination IP address, a source IP address, an authentication field, and other parameters of the service. The sender can be a client host, a BB, or a proxy. The RAA message contains the answer to an RAR PDU.

When a bandwidth broker receives an RAR message, it checks the authenticity, determines the egress router (interface) from its (inter-domain) routing tables, checks that the requested resources fall within the Service Level Specification (SLS), ensures that the domain has sufficient resources within it to support the flow, and determines whether the flow can or cannot be accepted according to the policies of the domain. If all of these constraints are met, the request is propagated recursively through the inter-domain path to the last BB. This last BB returns an RAA message to its BB immediately upstream, and the process continues until reaching the originating BB. Resources are confirmed by means of periodically sent refresh messages.

To configure border routers, bandwidth brokers must have access to them. SIBBS does not specify a particular protocol for this purpose, but it can use protocols such as DIAMETER (Calhoun et al. 2003), Simple Network Management Protocol (Case et al. 1990), or Common Open Policy Service (Boyle 2000).

COPS

The Common Open Policy Service, COPS, is a client/server protocol designed for policy-based network management. The basic model of COPS is presented in Figure 22.

The Policy Decision Point (PDP) is a central management entity, in charge of making policy decisions.

Figure 22: COPS basic model

The Policy Enforcement Point (PEP) is the point where the policies are applied, such as a router. The device can use the optional Local Policy Decision Point (LPDP) to make local policy decisions in the absence of a PDP.

COPS is a request/response protocol that allows a PEP (router) to interrogate its PDP about the action to perform once an event has occurred (for instance, if a signaling message arrived). COPS-SLS (Nguyen et al. 2002) is an extension to the COPS protocol for SLS management in a multi-domain environment. COPS-SLS basically has the same behavior as SIBBS: A request is propagated from one BB to the other in each domain on the data path. Each BB has a dual role: PDP role for its domain, and PEP role for the next domain BB.

Compared to SIBBS, COPS-SLS adds some features to the protocol, such as renegotiation of classes of service in case of failure of admission control. The COPS-PR protocol assures communication between BB and border routers (Chan et al. 2001). The discussion of bandwidth brokers and border routers is outside the scope of COPS-SLS.

MPLS Signaling Extensions

Multi-Protocol Label Switching (MPLS) originated in the mid 1990s to explore the performance of ATM switches in IP environments and now is standardized by the IETF in RFC 3031 (Rosen et al. 2001). Some of its predecessor protocols are IP switching (developed by Ipsilon), Tag switching (developed by Cisco Systems) and Aggregate route-based IP switching (developed by IBM).

Although, strictly speaking, MPLS is not a signaling protocol, it is an alternative approach to QoS-oriented signaling and, thus, it is included in this section. The main objective of MPLS is the support of quality of service through the use of predefined paths and adequate allocation of resources.

Main Characteristics

MPLS provides connection-oriented-equivalent QoS support by efficiently routing packets through preestablished paths, to which resources can be allocated based on service-level agreements and service-level specifications (SLA/SLS). By labeling packets and associating them with given paths, MPLS leads to a reduction in the amount of per-packet processing at each router. In addition, it eases traffic engineering, optimizes network utilization, and provides flow-based dynamic routing.

Basic Operation

MPLS-enabled routers (label-switching routers, LSR) switch and route packets based on a label appended to each packet. This clearly is simpler and quicker than IP routing. Labels define a unicast or multicast flow of packets, called Forwarding Equivalent Classes (FEC). Each FEC is allocated to a specific path consisting of a sequence of LSRs. Each FEC has a traffic characterization that defines the QoS requirements for the flow. A particular per-hop behavior can be defined at each LSR for a given FEC.

Prior to the beginning of a flow, a Label Switched Path (LSP) must be defined, either manually or by using an interior routing protocol (e.g., OSPF). Labels must be assigned for the various links that make up the path. Labels have local significance: Incoming packets with a given label are, in the general case, forwarded to the next link with a different label.

Figure 23 illustrates the basic operation of MPLS. This figure shows two FECs.

Labels

MPLS is said to be a Layer 2.5 technology because MPLS protocol control information (i.e., labels) are placed between layer 2 and layer 3 headers. MPLS labels are

Figure 23: MPLS basic operation

stackable. A packet may carry an unlimited number of labels, organized as a last-in-first-out (LIFO) stack. MPLS processing at LSRs is always based on the top label. Label stacking allows aggregation of LSPs into a single LSPs for portions of the route.

Each LSR in an LSP must assign a label to the LSP so packets belonging to the corresponding FEC can be recognized, inform upstream LSRs of the label assigned by this LSR to this FEC, and determine the next hop for the FEC and learn the label that the downstream LSR has assigned to this FEC.

Labels can be manually configured at each LSR or distributed using a label distribution protocol. Label distribution protocols establish a correspondence between FECs and LSPs and inform LSRs of label/FEC bindings. In addition, they negotiate LSR forms of interaction and advertise/negotiate MPLS capabilities.

Label distribution protocols are either extensions to existing protocol, e.g., extensions to BGP (Rekhter and Rosen 2001) or to RSVP, or specially developed protocols such as the Label Distribution Protocol, LDP (Andersson et al. 2001) or the Constraint Routed LDP, CR-LDP (Andersson et al. 2002).

CASE STUDY—EUQOS

The EuQoS Project

The EuQoS Project is a European IST FP6 Integrated Project, involving 24 partners (5 network providers, 5 corporations, 5 SMEs, and 9 research institutes). The motivation for the project is the increasing shift to the Internet Protocol in the vast majority of networks and the desire of telecommunications service providers to offer new added-value services to their customers. In this context, there is the need to coordinate the delivery of end-to-end quality of service driven by customer applications so providers may offer services that can respond directly to these application needs.

The general objective of the EuQoS project was to solve design issues associated with the delivery of end-to-end QoS service across heterogeneous networks. The main result of the project was the so-called EuQoS system, which supports the delivery of end-to-end quality of service, and encompasses network technologies, protocols, applications, and management.

The end-to-end QoS provision is achieved not only by end-to-end mechanisms and functions at the application layer but also at network-technology-independent and at network-technology-dependent layers. This requires the cooperation of a range of system features and functions that reside on end systems and on servers/network elements.

The Role of Signaling in EuQoS

The EuQoS project has a key central objective: end-to-end quality of service. Also, the project scope outlines several mechanisms, components, and approaches to be able to achieve this aim.

The basic mechanisms for end-to-end QoS provision are signaling and resource reservation. Signaling is carried out at various levels: end-to-end, at application level

through the use of SIP; hop-by-hop, at the inter-domain level through the use of NSIS complemented by routing and/or traffic engineering; locally, at the intra-domain level for resource management and provision through the use of COPS and technology-dependent mechanisms.

The EuQoS architecture is made up of a series of components that cooperate to achieve the end-to-end QoS provision goal. These components, called features and functions, make use of the mechanisms referred above in order to negotiate, manage and provide the required quality of service on an end-to-end basis. For example, the Signaling and Service Negotiation (SSN) function coordinates the use of the various signaling mechanisms (end-to-end, hop-by-hop, local) to support the establishment of QoS-enabled end-to-end sessions between user applications.

In the scope of EuQoS, two basic approaches for end-to-end quality of service provision are being proposed, developed, and studied: hard-model and loose-model approaches. The hard-model approach relies on inter-domain MPLS-based traffic engineering to accommodate traffic demands. This model is more appropriate for situations in which traffic needs are reasonably predictable and quite stable over time. The loose-model relies on the use of BGP routing, allowing for more flexible traffic support and being subject to possible constraints of resource availability.

Thus, it can be said that EuQoS addresses the end-to-end QoS problem in several dimensions, using a comprehensive methodology that explores complementarities and cooperation signaling mechanisms at various levels, system components cooperation, and inter-domain routing and traffic engineering.

Signaling and Service Negotiation

The main purpose of SSN is to provide the means for establishing end-to-end sessions according to user requirements. This requires a variety of signaling protocols in the various levels that make up the EuQoS control plane.

In EuQoS, the QoS provision is achieved by complex resource management and resource allocation, involving inter-domain and intra-domain signaling interactions. The EuQoS architecture has four different “signaling levels,” as illustrated in Figure 24.

The first signaling level pertains to applications. To establish, maintain, and release sessions with the required QoS levels, applications must express their needs and interact with the communication system, with the objectives of guaranteeing that these needs will be fulfilled, of adapting to network conditions whenever the available resources do not allow the initially requested level of QoS to be met, and of releasing the resources when sessions end. Application signaling uses the SIP protocol. SDP also is used to support session characterization.

To enable interactions between Level 1 signaling functions and Resource Managers (RMs), vertical interactions are needed. EuQoS-aware application proxies interact with RMs for technology-independent connection admission control and trigger Level 2 signaling for resource reservation. These interactions can be bidirectional, and RMs also can notify proxies of changes in network conditions.

The main objective of the Level 2 signaling functions is the support of resource reservation and management along

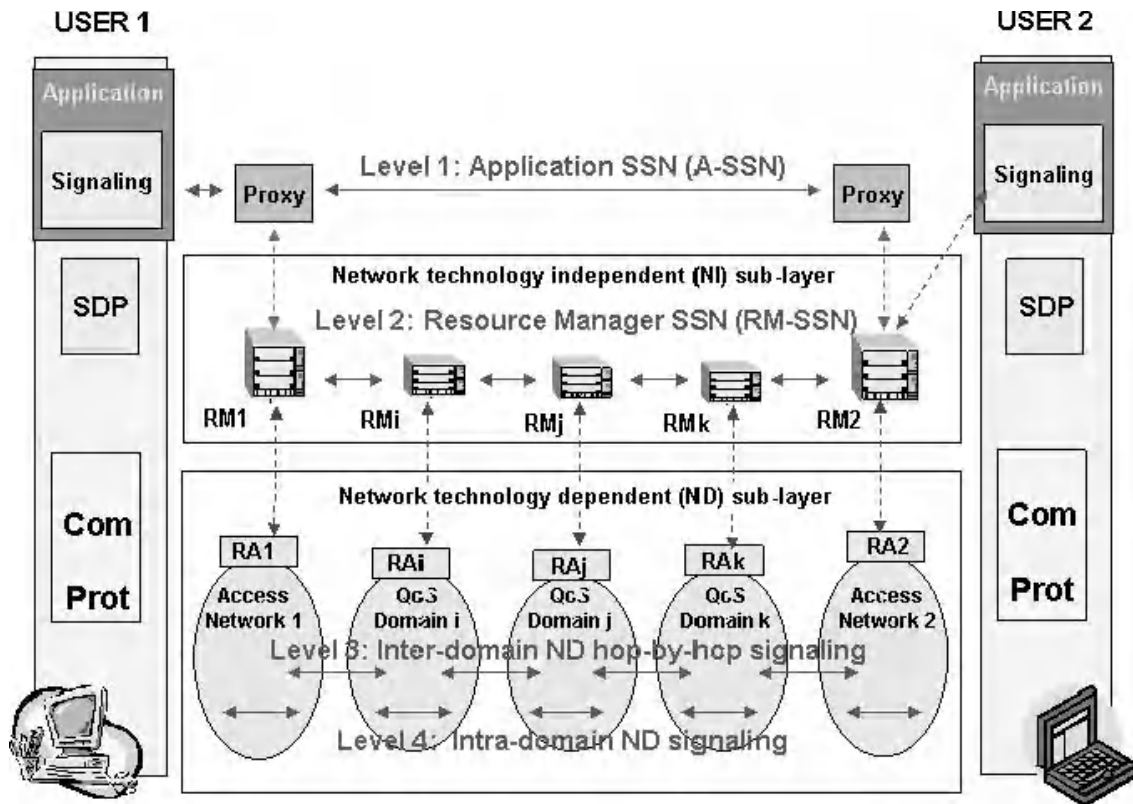

Figure 24: High-level view of the EuQoS signaling architecture

the data path across the various network domains. To enable domain administrative independence, Level 2 signaling functions operate on a hop-by-hop basis, between Resource Managers of adjacent administrative domains.

Level 2 signaling in EuQoS is based on NSIS. The vertical interactions between RMs and resource allocators (RAs) are supported on the COPS protocol.

Level 3 of signaling in the EuQoS architecture is the network technology-dependent (NTD) hop-by-hop inter-domain signaling. NTD hop-by-hop inter-domain signaling is commonly carried out by BGP (Border Gateway Protocol), which provides mechanisms for inter-domain traffic routing and enables the use of routing policies to control the exchange of routing information between different administrative domains (Autonomous Systems, ASs).

The definition of signaling mechanisms to be used at intra-domain level (the fourth signaling level) in the network technology-dependent layers is also in the scope of the EuQoS project. Knowledge about specific network-dependent signaling mechanisms has to be included in the domain's Resource Allocator to enable intra-domain resource management and QoS control.

Examples of intra-domain NTD signaling that RAs can use to configure network resources include RSVP and specific access network mechanisms such as ADSL bandwidth management, 3GPP, and Ethernet and Wi-Fi priorities. NSIS path-coupled also can be used for this level of signaling.

CONCLUSION

To avoid complexity inside the network, the Internet has been developed according to a data-driven approach—i.e., avoiding signaling as much as possible. Nevertheless, even the core Internet protocols, such as IP and TCP, do not work without some form of signaling functionality. ICMP is an IP-companion protocol that can be considered a signaling protocol. Many of the control mechanisms of TCP are signaling mechanisms.

Nowadays, the Internet is used for the support of countless applications with varying needs and characteristics. Internet elements must be managed, data flows must be secured, and quality of service must be provided to applications according to service-level agreements. All of this must be provided in a highly heterogeneous environment, as dynamically as possible. In this environment the original paradigm of keeping the network simple and free from signaling is not possible any more.

Signaling is indispensable for providing quality of service because QoS requires control over the existing resources. It also is indispensable for security, having an impact on NAT boxes and firewalls. With the advent of VoIP and of multimedia conferencing applications, in multipoint environments, signaling has become a key element of the current Internet.

In this chapter we have looked into the main signaling approaches and solutions for signaling. RSVP was developed as the supporting protocol for the Integrated

Services architecture for QoS provision. The Differentiated Service QoS architecture also requires some form of signaling, and this has also been dealt with here. Because of the growing need for signaling, the IETF is developing a comprehensive signaling framework, called NSIS, that has the potential to support the signaling needs of an unrestricted number of application areas, of which QoS and NAT/Firewall are the first cases. For voice, video, and multimedia applications, however, H.323 and, especially, SIP/SDP are the main solutions to session-oriented signaling. The future of signaling on the Internet certainly will include all of these.

GLOSSARY

COPS: Common Open Policy Service. COPS allows vertical signaling between Policy Decision Points (PDPs) and Policy Enforcement Points (PEPs).

GIST: General Internet Signaling Transport. GIST is a NSIS framework protocol for signaling transport between NSIS entities.

IETF: Internet Engineering Task Force. This is the organization responsible for the definition of Internet standards.

MPLS: Multi-Protocol Label Switching. MPLS is a protocol that supports traffic engineering (TE) using RSVP-TE extensions.

NATFW NSLP: NAT and Firewall NSIS Signaling Layer Protocol. This is the NSIS signaling protocol for NAT (Network Address Translation) and firewall transversal.

Network signaling: This is the exchange of data among network elements and end systems to support setup, maintenance, and release of network services.

NSIS: Next Steps in Signaling. This is the new signaling framework being standardized at the IETF.

RSVP: Resource Reservation Protocol. RSVP provides signaling for resource reservation in Integrated Services (IntServ) networks.

RTCP: Real Time Control Protocol. This signaling protocol enables synchronization of RTP (Real Time Protocol) flows.

SIP: Session Initiation Protocol. This is a signaling protocol for negotiation and maintenance of multimedia sessions.

INTRODUCTION

For the past few years, we have witnessed an increased deployment of multimedia traffic over the Internet. The triple play (voice, video, and data) services are taking shape using MPLS (multiprotocol label switching) as the core technology for integration. The standards and protocols for voice over MPLS have been developed by IETF (Internet Engineering Task Force), MFA Forum (formerly MPLS Forum) and the ITU-T (Telecommunication Standardization Sector of the International Telecommunication Union).

In this chapter, we focus on the deployment of voice over MPLS (VoMPLS) and VoIP (voice over IP) over MPLS (VoIPoMPLS). Voice and speech traffic is service sensitive because the packets delayed beyond the threshold time become unusable. Delays exceeding 400 ms are unacceptable, and the recommended maximum delay is 150 ms as per ITU-T recommendation G.114. On the other hand, some packet loss can be tolerated using redundant data to recover lost content and silence intervals to recover from problems. Since the TCP/IP network cannot guarantee the delay bounds of service-aware traffic, new protocols are developed that ensure the provisioning of required QoS (quality of service) using bandwidth allocation, traffic management, and fault handling. In the next section, we define the MPLS protocol as the core integration technology enabling QoS and traffic engineering in the network. The key concepts of MPLS are described and traffic treatment in an MPLS domain is discussed. MPLS serves as an enabling technology for QoS, and it works with DiffServ for prioritized handling of the QoS traffic. DiffServ is introduced, and the interworking of the MPLS-DiffServ network is explained.

Real-time VoIP and VoMPLS traffic has stringent requirements on the network, including zero packet loss, minimum delay, minimum jitter, and near zero call completion rate change (MFA 2004). In case of link or node failure, the network should recover within milliseconds to avoid any loss of communications. We discuss some of the protection schemes designed to meet these requirements and then look at the protocols and standards developed for VoIPoMPLS and VoMPLS. The enabling technologies, including codecs, signaling protocols, and transport

protocols, are defined. The last section covers the issues and challenges and the future for packetized voice.

MPLS AND DIFFSERV PROTOCOLS

Since IP routers work with statistical multiplexing, the datagrams do not follow a fixed path and may arrive at the destination out of order and with large variations of end-to-end delay under congested network conditions. These problems make conventional IP networks largely unsuitable for connection-oriented applications such as interactive real-time voice. MPLS (Rosen 2001) has emerged as the key integration technology for carrying voice, video, and data traffic over the same network. In an MPLS-enabled network, LSPs are installed from an ingress node to an egress node prior to start of transmission. Therefore, the connection-oriented applications can take advantage of the “virtual connections” set by MPLS. There may be several ingress-egress pairs in an MPLS domain resulting in a complex management challenge. Since the LSPs are stackable, traffic from different flows sharing some common characteristics can be aggregated on an LSP. These characteristics may include common egress and identical QoS and protection requirements. “Stackable” refers to the fact that each packet is treated as per the topmost label in the label stack. Therefore, two LSPs can be merged together by pushing the same label on top of the label stack for packets belonging to both LSPs. Various LSPs may also be aggregated and segregated based on the loading and the status of the network links. For example, in case of link failure, the Fast Reroute (FRR) protection trigger would reroute the traffic around the faulty link and merge with the original path forward of the downstream node of the faulty link. In this case, the downstream node would act as the PML (Protection Merge LSR) for the rerouted traffic, and it would swap labels to ensure that the rerouted traffic is handled transparently after the fault location.

MPLS operates by defining labels for the packets that belong to LSPs installed in the domain. An MPLS “shim header” is placed on the packet between the layer-2 and layer-3 headers. The 32-bit shim header is organized as shown in Figure 1.

MPLS Label (20 bits)	EXP (3 bits)	S (1 bit)	TTL (8 bits)
----------------------	--------------	-----------	--------------

Figure 1: MPLS header fields

The MPLS header fields include an unstructured 20-bit label that identifies the LSP to which this packet belongs. The label is assigned based on the FEC (forwarding equivalency class) of the traffic trunk. It is followed by 3 bits EXP (experimental) field and 1 bit indicating whether this is the bottom of the label stack. The TTL (Time to Live) field has the same usage as the TTL field in an IP header.

MPLS network runs constrained routing against traffic demands to find the most suitable LSP. Constrained routing involves computing the shortest path after pruning the network links that do not meet the requirements that may include reliability, bandwidth availability, cost, and delay. Constrained routing requires extended interior gateway protocols (IGP) such as open shortest path first-traffic engineering extensions (OSPF-TE) or intermediate system to intermediate system protocol-traffic engineering extensions (ISIS-TE). This capability to find the routes other than IGP shortest paths is known as MPLS-TE (MPLS traffic engineering) (Awduche et al. 1999). MPLS-TE achieves uniform distribution of traffic across the whole network, resulting in optimized utilization of the network. Once an LSP is installed, its minimum bandwidth is guaranteed on original and protection paths, and the status of all the links in the network is updated to reflect the bandwidth booking by the new LSP. LSPs are installed using label distribution protocol (LDP) or traffic engineering extensions of resource reservation protocol (RSVP-TE) defined by IETF. MPLS allows seamless integration with conventional IP networks because the MPLS header is removed by the egress router before forwarding the packet to the conventional IP network. The scalability offered by LSPs is unmatched even by asynchronous transfer mode (ATM) network because ATM offers only two levels of hierarchy as opposed to arbitrary number of levels in MPLS.

LSPs may carry different types of traffic, including e-mail messages, real-time stock quotes and bids, real-time biomedical data, real-time voice packets, FTP (file transfer protocol) packets, streaming video frames, and Web postings. In general, traffic can be categorized as elastic best effort and inelastic QoS traffic. The best effort traffic does not need any bandwidth, delay, and loss guarantees. On the other hand, QoS-sensitive traffic such as VoIP has certain minimum bandwidth and delay requirements. Therefore, the core routers should offer appropriate services based on the type of traffic involved. Class based queuing (CBQ) can be invoked on routers that implement

the differentiated services (DiffServ) protocol. DiffServ is defined by IETF in various Request for Comments (RFC) standard documents. CBQ allows routers to create separate queues for each outgoing link based on the class of traffic. The QoS traffic is placed in a high-priority queue and serviced first.

DiffServ divides the traffic into expedited forwarding (EF) and assured forwarding (AF) per-hop behaviors (PHBs). EF is the premium service offered under DiffServ. It is suitable for low latency and low jitter flows that maintain almost constant rate. EF flows receive a minimum guaranteed bandwidth even under most congested conditions. AF PHB is subdivided into four classes, each receiving a minimum bandwidth and each class getting subdivided into three drop preferences. The packets in microflows falling into one of the subclasses cannot be reordered where a microflow refers to an individual user application generated traffic. The router can choose to discard packets based on their drop preferences. Best effort traffic receives default forwarding (DF) behavior from the network without any bandwidth or delay guarantees. Each packet carries a PHB identifier that is used by the router to place the packet in an appropriate queue, and each queue is serviced as per its priority. DiffServ provides a mechanism to control the amount of traffic per PHB entering a domain through the use of shaper, marker, and dropper entities operating within the ingress node. The core routers identify the packet PHB and offer appropriate service accordingly. The type of service (ToS) field in an IP packet header is modified to carry the DiffServ class information as shown in the Figure 2.

Differentiated services codepoint (DSCP) is a field in the IP packet header for classifying the packet in one of the DiffServ PHBs. As seen in Figure 2, DSCP extends to 6 bits, allowing a total of 64 PHBs to be defined. However, practically, only 14 PHBs have been defined because of varying drop precedences with one EF, one DF and twelve AF subclasses. To indicate drop precedences, DSCP field is subdivided into PHB Scheduling class (PSC) and Drop precedence. The two ECN bits are for explicit congestion notification. With two ECN bits, only four values are possible for congestion notification. Values 10 and 01 are set by the sender to indicate ECN-capability. The value 00 indicates that the packet is not using the ECN mechanism, and the value 11 is used by a router to indicate congestion to the end nodes (Ramakrishnan et al. 2001). The DiffServ protocol follows the Internet model of keeping the network core simple. The core routers only determine

DiffServ codepoint (DSCP) 6 bits	ECN 1 bit	ECN 1 bits
----------------------------------	-----------	------------

Figure 2: DiffServ mapping in IPv4 ToS field

the DSCP and serve each packet according to the PHB to which it belongs. The complex functions of admission control, shaping, marking, and dropping are pushed to the edge routers.

In an MPLS-DiffServ network, the routers jointly implement various MPLS and DiffServ functions. The ingress router is responsible for determining an LSP for a new flow request. The QoS requirements of the new flow can be translated into DiffServ class assignment at the ingress. For this purpose, the EXP field in the MPLS shim header is used. As the EXP field is 3 bits in length, it can represent only eight different scheduling and drop precedences. Under MPLS-DiffServ (Le Faucheur et al. 2002), two types of LSPs are defined. E-LSP interprets the label field of MPLS shim header as the egress identifier and the EXP field as the DiffServ PSC (PHB scheduling class) combined with the drop precedence. On the other hand, L-LSP interprets the label field as the DiffServ scheduling priority and the destination. The EXP field in L-LSP is used to indicate only the drop precedence of the packet. The main difference between E-LSP and L-LSP is the aggregation feature in E-LSP resulting in scalability; however, some PSCs in an E-LSP may suffer because the bandwidth is reserved for the whole LSP (Fineberg 2003).

When the transmission starts, the packets belonging to an assigned flow are marked as per the DiffServ PSC (PHB Scheduling class) and labeled as per the LSP installed. When a core router receives a packet belonging to this LSP, the LSP label is swapped based on the pre-installed label table, and the packet is placed in an appropriate outgoing queue as per the DiffServ PSC identifier found in the packet. Figure 3 shows the placement of the DiffServ class identifier and MPLS label for an E-LSP.

Priority flows must be protected against link and node failures. In an MPLS domain, protection schemes are implemented to provide backup paths. The next section discusses some MPLS protection schemes. Another requirement is security and portability that can be ensured by using MPLS-based VPN (virtual private network) tunnels.

In summary, MPLS-DiffServ networks offer the following services that are of particular importance to VoIP and VoMPLS:

- Advance reservation of bandwidth through installation of LSPs
- Aggregation (Multiplexing) of similar flows by the use of stackable LSPs
- Priority handling through the use of DiffServ identifiers and CBQ on routers
- Fast and efficient fault handling by the use of MPLS-based protection schemes
- Security and portability through the use of MPLS-based VPN tunnels

MPLS PROTECTION SCHEMES

To guard against failures, a number of protection and restoration techniques have been proposed for MPLS networks. Protection and restoration are separate techniques that yield different results. *Restoration* reacts to a failure by computing the path around the failed node or link after the failure has occurred. On the other hand, *protection* is a proactive technique that precomputes and installs backup paths for the high-priority LSPs. In most cases, the protection paths may be utilized by best effort traffic that can be preempted if the original high-priority path fails. In case of extremely sensitive high-priority traffic, protection paths can be used to carry duplicate streams (1+1) so that the communication is assured even if one of the original LSPs fails. The other proposals include 1:1 (one backup LSP for each primary LSP), 1:N (one backup LSP for a group of primary LSPs), M:1 (a group of backup LSPs for one primary LSP), and M:N (a group of backup LSPs for a group of primary LSPs).

MPLS labels are stackable, so traffic can be switched from the primary LSP to the backup LSP or backup segment LSP by a simple push of a label. Because each LSP is destined toward a specific node, any link failures that occur before the egress can be resolved by the FRR (fast reroute) technique, which creates a bypass tunnel around the fault. The bypass tunnel would resolve the local failures without involving L3 (Layer 3 or network layer). If the bypass tunnel rejoins the primary tunnel at the next hop, it only protects against link failures. If the bypass tunnel does not join the primary tunnel until after several hops, the PML is configured to identify and remove the backup label so that the original tunnel is identified at the primary egress node. Issues pertaining to the bypass tunnel include the scope of the label space and modification of forwarding information base (FIB) entries. To avoid signaling for label exchange, global label space should be used for the domain. In case of failure, FIB entries in the router are modified to push the bypass tunnel first hop label on each packet carrying the primary tunnel label and to point to the new interface through which the traffic would pass (Suwala 2004).

In addition to FRR, protection paths in MPLS can be installed on a per link basis (SLB) or per path basis (DP). In SLB (Single Link Basis) protection, each link of the primary LSP is protected by a backup LSP that is computed after pruning the original link from the tree. Thus it results in comprehensive protection of all the links that are members of an LSP. In DP (Disjoint Path) based protection, each LSP is protected by a link disjoint global backup LSP that reaches the same egress as the original LSP (Conte et al. 2002). The SLB scheme is computation intensive as it installs “L” backup paths for an LSP consisting of “L” links.

MPLS Label (20 bits) (FEC Destination)	EXP (3 bits) (DiffServ PSC) 3 bits	S (1 bit)	TTL (8 bits)
---	--	--------------	-----------------

Figure 3: DiffServ PSC placement in MPLS E-LSP header

In MPLS, a global backup path may be established for a working path; however, the fault indication may be implemented with simple path continuity tests. Thus, it may result in larger recovery time. Using reverse backup (RB) can speed up recovery in the following way (Marzo et al. 2003). When an outgoing link goes down, the current node can utilize a reverse backup LSP to direct the traffic back to the ingress of the working path. This node can also propagate the fault indication signal (FIS) to the ingress in addition to the traffic that can now be directed through the global backup path. Thus no packets are lost, and the FIS is propagated to the ingress within the shortest possible time. The RB scheme is most suitable for loss-intolerant applications, and it protects against multiple failures. It may also help in achieving a better performance in a Voice over Packet (VoP) network where loss bursts can render the service unsatisfactory.

VOMPLS AND VOIPOMPLS MECHANISMS

VoIP is implemented with RTP. Voice segments are packetized with RTP headers and placed in UDP segments for onward transmission through the IP/MPLS network. On the other hand, VoMPLS (MFA 2001) removes the overhead associated with the protocol stack of VoIP and carries voice directly over MPLS. Figure 4 shows the comparison of protocol stacks in both schemes. VoIP has the clear advantage of providing end-to-end connectivity because the user-to-network interface (UNI) definition for bringing users in direct contact with MPLS networks is still not mature, and its specification was released only recently (ITU-T 2002). VoIP protocol stack results in large headers that can be compressed to reduce the overhead. VoMPLS is currently more suitable for core network where a number of voice calls can be multiplexed and carried directly over the MPLS.

In both VoIP and VoMPLS, it is required to convert the voice into digital format using any of the several codecs proposed. Signaling is also needed to establish, maintain, and terminate a call. Transporting the digitized voice requires special protocols that can handle the real-time characteristics of the speech traffic. The next sections discuss the signaling and conversion standards, transport protocols, and VoIP over MPLS and VoMPLS issues.

Figure 4: VoIPoMPLS and VoMPLS protocol stacks

Codecs

Several codecs have been proposed for encoding voice, including the pulse code modulation (PCM) based G.711, G.721, G.722, G.726, and G.727, and the code excited linear prediction (CELP) based G.729 (ITU-T, G.729.1). PCM-based codecs digitize voice samples for rates reaching up to 64 kbps. However, G.726 and G.727 can also work with variable rates. On the other hand, G.723.1 uses voice samples of 30 ms duration to produce 20 to 24 bytes, resulting in rates of 5.3 kbps to 6.4 kbps. High-complexity coder G.729 is based on conjugate structure algebraic code excited linear prediction (CS-ACELP) algorithm, and it has a coding rate of 8 kbps with 80 bits every 10ms. The code-excited codecs take advantage of the properties of the human conversation to produce a much lower bit rate.

High bit rate codecs, such as G.711, G.726, and G.728, are found to produce very good mean opinion score (MOS) values meaning low voice degradation (Duysburgh et al. 2001) even in loaded best effort network conditions. It was determined through experiments that compressed adaptive differential pulse code modulation (ADPCM) codecs (G.721, G.722, G.726, G.727) yield end-to-end delays close to uncompressed PCM delays. The G.711 u-law codec has a higher compression/decompression delay and higher bit rates as compared to ADPCM codecs making it unattractive. However, the MOS scores for u-law codecs are better than those for ADPCM codecs (Zeadally et al. 2004). It is argued that uncompressed voice may be suitable in the intranet where higher bandwidth connections are available to save on the extra compression and decompression processing. In wide area VoIP implementations, G.729 has generated considerable interest because of its good quality and low bit rate. As opposed to PCM high bit rate codecs used in PSTN, G.729 is capable of taking advantage of the 60 percent silence periods in a conversation to reduce its effective rate to about 3.2 kbps (Scheets et al. 2004). This reduction in bandwidth is made possible by detecting voice presence or absence in a sample and not transmitting during silence periods. The receiver fills in comfort noise during the periods when G.729 transmitter is not sending any samples to avoid the dead line effect. However, this reduction in bandwidth turns the constant bit rate flow into variable rate flow.

SIP and H.323

H.323 is a comprehensive protocol introduced by ITU-T to allow real-time multimedia conferencing on the Internet. H.323 is a collection of various standards and protocols that allow the end users to choose the codecs, connect and register with the gatekeepers, route to the PSTN network through gateways, and encapsulate and transmit media by using RTP over the Internet. H.323 includes the following:

- H.225 registration, admission and status (RAS) protocol for registration with the gatekeeper
- H.225.0 for data transportation
- H.245 for connection management
- Q.931 signaling channel
- Optional video support through H.261

Figure 5: H.323 devices

H.323 zone gatekeeper is an entity on the network that translates H.323 IDs and PSTN phone numbers into IP addresses. It coordinates the admission of end points into the H.323 network by using the RAS protocol. RAS messages are exchanged between gateways and gatekeeper using UDP. The gateways are the interface between the PSTN and the IP network. The gatekeeper also performs bandwidth management and control, and it may reject calls when the appropriate bandwidth is not available. Call control and setup signaling is carried out between gateways via the gatekeeper or directly using Q.931 signaling messages. Following are some example steps in the H.323 call setup process, which are based on H.323 working descriptions (Cisco, ID5244). The devices mentioned in the explanation are illustrated in Figure 5. It is assumed that the call is being placed between two PSTN phones namely Telephone1 and Telephone2. Telephone1 is connected through Gateway 1 (GW1) to the H.323 zone, and Telephone2 is connected through Gateway2 (GW2) to the H.323 zone.

1. The gateways periodically attempt to discover the zone gatekeeper. After the gatekeeper is discovered, gateways register with an e-mail address or a phone number.
2. A new phone call across the H.323 network originates from Telephone1, and it touches GW1 first, which forwards it for acceptance to the gatekeeper.
3. The gatekeeper looks up the destination in its tables and consults peer gatekeepers in other zones until the destination is determined. Some vendors implement a centralized directory gatekeeper to keep the architecture scalable. In this example, the call is intra-zone, and the gatekeeper finds the destination gateway, which is GW2, in its tables.
4. The gatekeeper informs the origin gateway GW1 about the coordinates of the destination gateway GW2.
5. The origin gateway GW1 sends a call setup request to the destination gateway GW2.

6. The destination gateway GW2 requests clearance of the new call from the gatekeeper of its zone.
7. On receiving clearance, the destination gateway GW2 places a call to the destination PSTN phone Telephone2.
8. On connecting to the destination phone, the destination gateway GW2 sends a connection confirmation message to the origin gateway GW1.
9. When one of the parties hangs up, the related gateway sends a control message to the gatekeeper of its zone and another control message to the other gateway. For example, if Telephone1 hangs up, GW1 will send control messages to the gatekeeper of this zone and GW2.
10. The other gateway informs the gatekeeper of its zone about the call termination and sends a call disconnect signal to the other party through the PSTN network. Continuing the example of disconnection initiated by Telephone1, GW2 will inform the gatekeeper about call termination and indicate call disconnection to Telephone2.

SIP (Session Initiation Protocol) is a signaling protocol introduced by IETF (Rosenberg et al. 2002) for real-time multimedia communications over the Internet. SIP has a limited scope as compared to H.323. SIP specifies the call initiation, management, and termination mechanisms and does not mandate the use of any specific transmission protocols or codecs. Two primary categories of devices in SIP are servers and user agents. A SIP registrar is equivalent to an H.323 gatekeeper in functionality as it registers each SIP user and provides coordinates of a user when a call request is received (Kurose and Ross 2005). The SIP proxy server manages signaling and works in conjunction with the SIP registrar to return the appropriate response to the caller. SIP does not provide direct support for interfacing to PSTN as opposed to H.323. SIP commands are text based, thus making it easy to develop SIP-based

applications. Both H.323 and SIP allow selection of any codec, and both communicating parties need not use the same codec. Following are some steps in registering SIP clients and using SIP to establish voice calls with other SIP users:

1. On initiation, a SIP device (user agent) sends its coordinates to the SIP registrar and periodically refreshes this registration information.
2. When a SIP device wants to call another SIP device, the caller is termed as user agent client, and the called party is termed as user agent server. The caller sends the INVITE request to the SIP proxy server.
3. The SIP proxy server returns the most recent coordinates of the called party as obtained from the SIP registrar.
4. Using the location as returned by the proxy, the caller establishes direct connection to the called party for exchanging media bytes.
5. Any of the parties engaged in a call can terminate the call by sending a call termination request that is acknowledged by the other party.

VoIPoMPLS and VoIP Issues

VoIPoMPLS involves encapsulating the coded voice bytes into the RTP packets and transmitting over the UDP/IP/MPLS protocol stack. The combined count of header bytes for RTP, UDP, and IP is 40 bytes. Figure 6 shows the voice data together with L3 and above headers. For MPLS VPN transporting voice, this overhead reaches 48 bytes and exceeds the payload size. Therefore, it is very important to multiplex different voice packets and to compress the header. Voice packets that belong to the same connection can be multiplexed together in one MPLS frame. However, it would require extra wait time at the sender side before transmitting the multiplexed frame. Thus, this option has to be carefully exercised given the delay budget of VoIP. Various header compression techniques have been proposed, including compressed RTP, enhanced compressed RTP, and robust header compression. Also, composite IP (CIP) and lightweight IP encapsulation (LIPE) concatenate voice packets together (Vázquez 2004). With RFC 2508 (Casner et al. 1999) compression of RTP/UDP/IP headers, the header length reduces to 2-4 bytes. Other issues in VoIP include jitter removal, silence suppression, echo cancellation, serialization delay, and loss recovery. We discuss each issue briefly and point out the solutions proposed.

Jitter

Jitter is the unwanted variation in end-to-end delay that results from indeterministic queuing delays in routers.

Jitter can cause the VoIP service to fail. Jitter can be smoothed out by using a jitter buffer, but the jitter buffer tends to increase the overall end-to-end delay. Jitter can be removed by service-aware routing, assigning highest priority to speech traffic and bandwidth allocation through the use of MPLS and DiffServ.

Silence Suppression

Silence suppression seeks to save on the network bandwidth by not transmitting the voice packets during the silence intervals. However, to avoid the “dead line” effect, it is important to use CNG (comfort noise generation) when the receiver does not get any voice samples from the sender. The sender deploys VAD (voice activity detection) to scan each sample and determine if voice is present or not.

Echo

Echo is an annoying effect in conversation, and it may be caused in VoIP by coupling between a microphone and a speaker and line cross-talk (Scheets et al. 2004). The most difficult type of echo is the one produced by the use of independent microphone and speaker in VoIP conversations as done by most PC users today. Echo can be controlled and reduced by the use of echo canceller filters that detect and filter out the copies of the original signal. Such filters can be programmed into codecs that digitize the voice. Increased end-to-end delay causes the perceived echo signal level to increase, and thus the filters may not work correctly. Noise reduction and automatic level control techniques are part of the G.169 standard (ITU-T 1999) for alleviating these problems. Noise reduction techniques work on suppressing nonvarying noise by learning the spectral frequencies of the noise and filtering out the same. ALC (Automatic Level Control) involves keeping the transmitted signal at a predetermined level by adjusting the gain and loss.

Serialization Delay

Serialization delay is caused by the placement of packets on the serial network path. On the receiving end, the bits on the serial line are then captured and converted back to packets. Faster hardware has evolved reducing this type of delay.

Speech Traffic Loss

Finally, it is not critical for speech traffic to arrive without any loss because up to 10 percent loss in the original uncompressed data is reported to have no effect on the perceived quality of speech (Kostas et al. 1998) provided that the data is not highly compressed. However, loss burst may affect the conversation in an adverse way. Loss bursts of a small number of packets may be corrected

IP Header (20 bytes)	UDP Header (8 bytes)	RTP Header (12 bytes) plus optional RTP mux	Voice Data (40 bytes for G.711 at 64 kbps)

by the use of the forward error correction (FEC) techniques that add redundant information to packets or perform interleaving to reduce the burst errors. In case of holes in the received stream, FEC techniques can plug the holes with reduced quality speech recovered from FEC chunks in the packets.

RTP and RTCP

RTP (Schulzrinne et al. 2003) and RTCP (Real Time Control Protocol) (Schulzrinne et al. 2003) have been developed to facilitate the transmission of time-sensitive traffic over the Internet. RTP is the actual transmission protocol that works above UDP.

The voice data at the sending side is concatenated with a header that identifies the codec used and specifies the time stamp and sequence number. Some of the fields in the RTP header are shown in Figure 7 and explained here:

- The Payload Type field identifies the encoder used for VoIP out of various codecs discussed earlier.
- Each RTP segment is numbered sequentially, and the number is placed in the Sequence Number field.
- The time stamp is taken from the sender clock, and it reflects the time at which the first byte in the voice data was sampled.
- Synchronization source identifier (SSRC) is a random number generated and attached to a stream when a new stream starts to get transmitted. Optionally, contributing source identifier (CSRC) can be added ahead of SSRC if multiplexing of various streams is performed.
- Extra information can be attached using the next field, and possibly an extension header can be added by the application using RTP.

RTCP is a protocol that works in conjunction with RTP to provide valuable feedback to each participant. RTCP opens a port numbered one higher than the RTP port and periodically allows the receiver to send statistics of the session to the RTP sender and vice versa. RTP sender can use the information from the receiver to readjust the rate in order to decrease the losses. The RTCP packets contain statistics of packets sent/received and lost as well as jitter for a particular session identified by SSRC. To contain the amount of control traffic to a minimum, RTCP limits

the frequency of its packets so that the overall bandwidth usage is less than or equal to 5 percent of the total bandwidth used by the session.

VoMPLS

VoMPLS refers to the scenario in which the voice packets are directly transported over the MPLS without the use of RTP/UDP/IP protocol stack. As seen earlier in Figure 4, the VoMPLS protocol stack is more compact as compared to VoIP. Two types of frames are defined in VoMPLS: primary and control frames. The VoMPLS primary frame header is shown (MFA 2001) in Figure 8.

VoMPLS primary frame header is 4 bytes long and includes 5 fields:

- Channel Identifier uniquely identifies the voice channel that is the source of the payload. Thus, a total of 248 different voice calls can be multiplexed into a single LSP.
- Payload Type identifies the encoding scheme used as well as silence removal/insertion descriptors. A value equal to or above 224 indicates control payload (part of the control frame) that would allow DTMF (dual tone multi frequency) dialed digits as well as signaling for the channel to be carried (Fjellskål 2002).
- The revolving Counter field is set at the first sample or frame and keeps incrementing for each additional frame.
- Payload Length is read in conjunction with the pad length to keep the payload a multiple of 4 bytes.

Multiple LSPs can be aggregated with the use of optional inner MPLS labels in addition to one mandatory outer MPLS label. The VoMPLS control frame header is also 4 bytes in length, and the fields in the header are shown in Figure 9.

The Payload Type field distinguishes between dialed digits and the channel related signaling. Time Stamp is relative to the first randomized time stamp. The Redundancy field is very important to ensure the receipt of the control frames. If the Redundancy field is set to 0, 1, or 2, the control packet is repeated that many times.

Another solution for VoMPLS reuses ATM Adaptation Layer 2 (AAL2) components but replaces ATM by MPLS (ITU-T 2002) (MFA 2003), thus eliminating the ATM cell overhead. The MFA 5.0 implementation agreement

Channel Identifier (8 bits)	Payload Type (8 bits)	Time Stamp (16 bits)	Redundancy (8 bits)
--------------------------------	-----------------------------	----------------------------	------------------------

Figure 9: VoMPLS control frame header format

MPLS Label Stack	A2oMPLS Header			CPS Packet Header			
	Reserved	Length	S No	CID	LI	UUI	HEC

Figure 10: A2oMPLS and CPS header in MPLS frame

proposes voice trunking over MPLS by directly encapsulating AAL2 common part sublayer (CPS) packets into MPLS (A2oMPLS). The gateway to the MPLS network should be able to function as an AAL2 switch. Multiple A2oMPLS connections can be multiplexed into a single LSP. One MPLS frame may carry multiple CPS packets. The detailed header fields are shown in Figure 10.

The following fields are included in the A2oMPLS header:

- Reserved (10 bits) currently ignored.
- Length (6 bits) used for padding length. It is set to 0 if A2oMPLS packet length exceeds 64 bytes.
- Sequence Number (S No) (16 bits) used if guaranteed ordered packet delivery is required. Sequence number of 0 indicates otherwise.

The following fields are inside the CPS packet header; several CPS packets may be packed in one MPLS frame.

- CID (8 bits) identifies the A2oMPLS connection carried. Thus a total of 248 connections (8 to 255) can be multiplexed into a single LSP.
- LI (6 bits) identifies the length of the CPS packet.
- UUI (5 bits) is used for user-to-user indication (0 to 27 for users, 30-31 for layer management, and above 31 reserved).
- HEC (5 bits) (header error control) uses CRC checksum. However, this field may not be used in the MPLS environment.

The AAL2 is suitable for transport of streams for which the bit rate may be variable, but they require bounded delay guarantees. Examples are the compressed voice and video streams. Several streams of AAL2 can be multiplexed into a single MPLS LSP using the A2oMPLS implementation agreement.

THE ROAD AHEAD FOR VOIP AND VOMPLS

VoP (Voice over Packet) is emerging as the most preferred method of transporting voice calls. Packetized voice is flexible as different voice calls can be multiplexed in the

core and encrypted to ensure privacy. The service providers can use most of the deployed bandwidth for profit and the users pay only for the services that they use. Traditional Internet was unable to support the voice traffic with QoS guarantees. VoIP had to work under the best effort scenario, utilizing dejitter buffers to minimize jitter and put packets in order. Loss recovery was implemented using interleaving and adding redundant information to the packets. Even with these corrective measures, the user-perceived quality was poor. With the introduction of new protocols such as DiffServ, MPLS, and MPLS-TE, it has become possible to achieve performance closer to the toll quality voice as in PSTN.

Industry is converging on MPLS as the protocol of choice for voice, video, and data transmission over the Internet. MPLS is adaptable to various QoS demands and allows stacking of LSPs for scalability and aggregated treatment. VoIPoMPLS deploys voice over the RTP/UDP/IP protocol stack, which uses MPLS tunnels. VoMPLS runs voice directly over MPLS, reducing the protocol tax. VoIPoMPLS with compressed headers is a viable option for providing the Internet telephony to the end users as the overhead reduces to a minimum. VoMPLS is well suited for multiplexing in the core and carrying the bulk of voice calls through the MPLS domain. If the MPLS user-to-network interface (UNI) is implemented widely in the near future to allow the users to connect directly with the MPLS network, it may take VoMPLS to the end users with new possibilities. An important consideration is to segregate the best effort traffic and QoS traffic in the core of the network to reduce the possible delays and loss due to the congestion resulting from data bursts on shared links. Work has been done to automate the segregation of traffic in an MPLS-DiffServ domain (Zubairi 2002), and further enhancements are needed to fully automate the segregated allocation of bandwidth to the MPLS tunnels.

Some of the challenging issues in implementing VoIP include the suppression of echo, location-aware E911 emergency services, uninterrupted power for VoIP phones, making VoIP intruder safe, and porting numbers. We discuss some of these issues here:

- The VoIP security threats include fraud related to billing and unauthorized usage by stealing the service. WLAN-based telephony gives rise to major security problems because WLAN is mostly open and unencrypted.

MPLS-based VPNs can be used to ensure security and privacy for VoIP calls.

- The FCC had mandated the E-911 service (FCC 2005) for VoIP phones by November 2005, but this deadline is now pushed back by four years because of problems in implementing the user location detection in VoIP phones.
- Because VoIP phones are operated with utility power, blackouts and brownouts may leave customers disconnected. Therefore, efforts are under way to ensure uninterrupted service for VoIP.

The efforts to provide uninterrupted power can benefit from the recent interest in extending MPLS into the wireless network and especially 3G UMTS (universal mobile telephone service). It is expected that in the near term, there will be an increased VoIP implementation in the cellular network. The IMS (IP multimedia subsystem) specification has generated a lot of activity for enabling quad play services, making video phone calls a closer target that can be achieved with increased bandwidth in wireless networks. IMS is a modular platform that is based on IP and SIP. If the quad play continues to grow, the traffic mix in future networks would change to mostly delay bounded VBR (variable bit rate) streams, causing the interest in MFA IA 5.0 (MFA 2003) and similar standards to increase. MFA IA 5.0 is specified by MFA Forum as a standard for voice trunking over MPLS. It is believed that the next generation interactive telephony will be based on MPLS, and it will allow transparent connectivity through landline and mobile networks. The user will be able to continue the conversation while changing the connection from landline network to mobile network. The VoP phones would be flexible and allow all the functionality of current PSTN phones. The most significant new functionality would include multiway audio and text conference calling, videoconferencing, and several options for security and encryption.

GLOSSARY

- IETF:** Internet Engineering Task Force is an open volunteer organization that develops Internet protocols and standards.
- IMS:** IP multimedia subsystem is a SIP-based standardized architecture developed to merge multimedia services in IP and cellular networks.
- ITU-T:** International Telecommunications Union-Telecommunication Standardization Sector is a body that produces telecommunication standards for ITU.
- MFA Forum:** MPLS and Frame Relay Alliance Forum is an international association of telecom and networking companies advancing deployment of multiservice packet-based networks.
- MPLS:** Multiprotocol label switching is a mechanism to implement connection oriented and regulated services over the connectionless TCP/IP-based Internet. IETF and MFA Forum are responsible for advancing MPLS standards.
- QoS:** Quality of service is the probability of meeting the goals of reliability, timeliness, and delivery of packets in a network.

RTP: Real time protocol is a standard format for delivering multimedia over the Internet.

SIP: Session initiation protocol is a signaling protocol for multimedia conferencing over the Internet.

VoIP: Voice over IP is the routing of voice phone calls over the Internet fully or partly.

VoMPLS: Voice directly over MPLS is the routing of voice calls over MPLS instead of voice over IP over MPLS.

VoP: Voice over Packet is a general term that covers VoIP, VoIPoMPLS, and VoMPLS.

VPN: Virtual private network is a private network configured over the public Internet. It allows remote users to connect to their corporate network as if they were local users.

WLAN: Wi-Fi (IEEE 802.11) based wireless local area network that allows users within the range of radio waves to connect to the network.

INTRODUCTION

Depending on whom you ask, “ENUM” is short for “tElephoneNuMberMapping,” “E164NuMberMapping,” or “Electronic NuMbering.” Although the name may have multiple interpretations, ENUM is clearly defined as a use of the *domain name system* (DNS) for storage of telephone numbers to identify available services connected to one telephone number.

The advent of Internet services has broadened the range of possibilities for routing communications as well as brought an explosion in the number of common contact service types. Anyone who uses the Internet is likely to have more than one e-mail address, instant messaging identity, telephone number, and so on. To make matters more complicated, most Internet users will not have addresses for every contact service type. This leads to a basic challenge of discovering what services are available for a given user so that a mutually agreeable contact form can be used for any given communication. ENUM provides that discovery service by giving end users the ability to use one reference to locate several types of (current) contact information. ENUM serves its purpose by tying an existing, globally deployed contact identifier to other related contact identifiers in a way that is globally accessible and usable by communications systems software. In other words, given a person’s telephone number, ENUM enables a user’s desktop software to find the appropriate instant messaging or e-mail coordinates to connect with another person using the appropriate services. Figure 1 illustrates a sample scenario.

Generally speaking, ENUM uses DNS to store information within the network so that coordinates for one or more contact services are globally accessible for each telephone number.

ENUM is not unique for using the DNS for mapping from identifiers to resources other than traditional host names to *Internet protocol* (IP) addresses. For example, *uniform resource names* (URNs) (Moats 1997) use DNS to map non-host name identifiers to network-accessible

Figure 1: Generally speaking, ENUM uses DNS to store information within the network so that coordinates for one or more contact services are globally accessible for each telephone number

resources. ENUM leverages DNS technology that was originally developed for URNs. ENUM is not even the first effort to map telephone numbers into DNS: *tcp.int* was established in the early 1990s “to provide transparent mapping between general-purpose computers on the Internet and special-purpose devices directly connected to the telephone network” (Malamud and Rose 1993). ENUM is a particular mapping proposal designed to address, in ways not answered by any existing technology, the motivations of several interests that converged in the late 1990s.

After a brief review of motivations for ENUM, this chapter will outline the details of the ENUM specification. Although the basic ENUM technology is straightforward in its specification, there is a lot of latitude in configuring and deploying it. To be able to achieve the desired effect, it is important to understand what is intended in the technology and how the pieces fit together. The reader will obtain a working understanding of the technology; advanced readers will obtain further insight into the specifics of the technology usage. The chapter will further discuss ENUM deployment realities from an operational and case history perspective. Finally, some insight into

the future development of ENUM is provided in the closing section.

ENUM MOTIVATIONS

Just as there are multiple interpretations of the name “ENUM,” there are different, largely compatible, motivations for the application of the technology. Two classes of motivations are described below.

Managing in a World of Multiple Contact Services

One of the most ubiquitous pieces of modern technology is the telephone. From a young age, we learn to recognize phone numbers and know that all we have to do is pick up a phone, dial the digits, and expect to speak to the person or service associated with the number. In our daily lives, other means of communication continue to become ever more prevalent: e-mail, instant messaging, and so on. Each new technology form brings a new address to remember. How can we manage all of these addresses, providing our own contact data as well as knowing where to reach people for each communication medium?

The ENUM standard provides the facility to associate and look up communication services associated with any given telephone number. Specifically, telephone numbers are mapped into DNS names. The corresponding DNS records hold data about specific services and uniform resource identifiers (URIs) to access them.

Specifically, ENUM supports the mapping telephone numbers to contact service URIs, allowing multiple contact coordinates (of different service types) to be associated with any number (see Figure 2).

In the late 1990s, when ENUM work was started, there was still a general desire for some form of standardized, widespread information infrastructure services. However, even though “spam” was not yet a debilitating problem, most of the world had given up hope for the possibility of creating a “global white pages service” to search for a person’s e-mail address or other coordinates. Deploying new infrastructure information services was perceived as being challenging at best, minimally requiring a strong

Figure 2: Specifically, ENUM supports the mapping of telephone numbers to contact service URIs, allowing multiple contact coordinates (of different service types) to be associated with any number

Figure 3: With ENUM, it is possible to publish one telephone number and yet be reached through a variety of voice communication mechanisms. This example illustrates support for connections via telephony at a different telephone number (in a different country), or using SIP-supported voice over IP

corporate interest (which tended to be at cross-purposes with the desire for global interoperability).

ENUM was never designed as “the global whitepages service,” but it had to address the same challenges as it sought to enable global dynamic discovery and retrieval of service contact point information associated with identifiers assigned to individuals or organizations. Therefore, ENUM leveraged two established, deployed, and managed global infrastructures: international telephone numbers and the domain name system.

Routing Telephony in the Internet Age

The discussion above treads lightly around the subject of telephony. One of the more obvious motivations to pursue ENUM is to facilitate the mapping between telephone numbers (dynamic number portability); another is to support *voice over IP* (VoIP).

With ENUM, it is possible to publish one telephone number and yet be reached through a variety of voice communications mechanisms (see Figure 3). This example illustrates support for connections via telephony at a different telephone number (in a different country), or using *session initiation protocol* (SIP) supported VoIP.

Discussion of VoIP brings to light another facet of ENUM: It has application beyond a user’s desktop. An ENUM client could equally be used by telephony gateway software or other VoIP network infrastructure elements.

With this, ENUM brings the world of VoIP and traditional telephony together in ways that challenge established business models and mechanisms for managing or controlling call routing. This makes ENUM a matter of considerable interest to carriers as well as national regulators and the International Telecommunications Union.

ENUM TECHNOLOGY

The preceding sections outlined the goal and motivation for the ENUM technology. Engineers began discussing possible approaches in Internet Engineering Task Force (IETF) meetings in 1998 and formed the ENUM Working Group in 1999. Its job was to develop a standard specification for the technology; to achieve global deployment

and accessibility, open specifications and interoperability are required.

This section will outline the explicit and implied requirements identified for the ENUM technology and then describe the technology framework and the standard developed by the ENUM Working Group.

Requirements and Applicability

ENUM does not set out to be the only solution in managing multiple contact coordinates. It started from some specific implicit and explicit requirements that are important to understand in order to determine its ultimate applicability. These are detailed as follows.

Software Accessibility: ENUM is intended to provide a service to communications software. This requires structured data exchanges as opposed to a Web interface to do searches.

Public Use: The data provided in ENUM is public and for public use. Any constraints on access (to the contact services, for example) are provided by the contact services rather than by restricting the ENUM access for determining the contact addresses.

Contact Look-Up but Not Updating: The emphasis in ENUM is in providing the ability to look up contact information. Although it must be possible to update the contact information in a reasonable time frame (e.g., minutes not weeks), ENUM does not specifically address how information updating is done.

Global Identifier: The identifier used as the key in ENUM must be global in scope—that is, whatever identifier is used must be usable everywhere in the world.

Global Accessibility: It must be possible to carry out an ENUM lookup from anywhere in the Internet, and the set of results (list of contact service information) should be the same from all points of the Internet. In that vein, any ENUM result set should be uniformly interpretable—in a standards-based form—to support the interoperability of software and services. Note, however, that the contact services returned by an ENUM query may vary in terms of reachability (for privacy or other reasons).

Dynamic Data: It must be possible to update the identified contact services independently of distributing the ENUM identifier. In other words, the identifier itself in no way constrains the set of possible contact services that are available at one point in time or the next.

Distributed Management: It must be possible to delegate the management and administration of ENUM and contact services for identifiers or groups of identifiers. The goal is to allow management of the ENUM responses to occur as close to the owner of the identifier as reasonably possible. It must also be possible to delegate the management of portions of the whole set of identifiers to different groups if partitioning of the space is needed to meet different legal and social requirements.

Unconstrained Contact Services: It must be possible to use ENUM to connect to a wide range of contact services: not just VoIP, voice over landlines, or e-mail. And it must be possible to add new contact services as technologies are developed and deployed.

Solution Framework

All that is needed to appreciate the ENUM technology is an understanding of three things:

1. ENUM is all about mapping one globally unique identifier (international telephone numbers) onto an Internet infrastructure system that is designed to manage and serve up data for hierarchical, globally unique identifiers (the domain name system);
2. what data can be stored within the DNS to provide pointers to associated contact services; and
3. how the telephone number and the DNS hierarchical resolution and management structure allow distributed control of the ENUM infrastructure to keep data in the hands of the appropriate owners.

This section will discuss those points in general, and the next will provide more specific technical details.

Telephone Number DNS Mapping

It is important to see the similarities and differences between telephone numbers and domain names in order to understand ENUM's chosen mapping between them.

International telephone numbers are defined by ITU-T recommendation E.164 (International Telecommunications Union 1997). The first one to three digits represent the country codes (top of the hierarchy). The organization of the remaining digits into area codes (where used) and exchange identifiers depends on rules established for each country or operating body. This structure is generally opaque to the common telephone user. The important points to note about the number are:

- the top of the hierarchy is at the left-hand side of the string of digits;
- the E.164 number does not explicitly indicate the separation of components in the hierarchy (country, area code if used, and exchange); and
- the separation varies from one country code to another, so there is no single general way to parse an E.164 number without knowing the rules specific to the country code.

By contrast, domain names are explicitly organized by hierarchical components, and the top of the hierarchy is expressed in the right-most component: the top-level domain (e.g., “com” or “org”). So,

- the top of the hierarchy is at the right of the domain name component sequence;
- the domain name does explicitly indicate the separation of components (with a period or “dot”); and
- although there are different approaches to assigning domain names from one top-level domain to the next, it is possible to write a single generic parser of domain name components.

Therefore, to map E.164 telephone numbers onto domain names, the direction of hierarchy had to be matched and something had to be done to allow the variable length

(administrative) components to be preserved within the E.164 number. To achieve this mapping, all nondigit characters (except “+”) are removed from the E.164 number string, the resulting string is reversed, and each digit is represented as a separate domain component in the domain name. All such domain names are rooted at “e164.arpa.”

For example, the E.164 number

+44-163-296-0083

is converted to the domain name

3.8.0.0.6.9.2.3.6.1.4.4.e164.arpa.

ENUM Contact Service Information

With the mapping between E.164 number and DNS name in hand, the next step is to look at how ENUM uses the DNS to store contact service information.

ENUM maps telephone numbers onto DNS names for the purpose of using the DNS to retrieve contact service information associated with the telephone number. As described in Chapter 81 of this volume, information is retrieved using the DNS by resolving the domain name and getting a set of structured *resource records* (RRs) as a response. Therefore, an important part of the ENUM standard is specifying how contact service information can be stored in DNS RRs.

ENUM makes use of a particular DNS RR type: the *naming authority pointer* (NAPTR). As described in more detail in the section below titled “The ENUM Standard,” each NAPTR RR associated with the name being resolved includes a “service” field that indicates which contact services’ coordinates are provided from the NAPTR record. For example, one NAPTR record might provide directions to a number’s SIP contact service. Another, for the same number, might provide the coordinates for e-mail contact. At any given time, there is a fixed set of these service types. They are specified publicly and listed with the *Internet Assigned Numbers Authority* (IANA) to ensure interoperability and compatibility between software implementations (clients and servers). The purpose of the IANA registry is to allow orderly extension of the set of accepted types.

In the most typical case, the NAPTR record provides the coordinates for a service by directly including a mapping to the relevant URI for the service. For example, a NAPTR record for “3.8.0.0.6.9.2.3.6.1.4.4.e164.arpa.” might provide the URI “sip:info@example.com” for the “SIP” ENUM service type. Another NAPTR record for the same name might provide the URI “mailto:contact@example.com” for the “email:mailto” ENUM service type.

Making Use of the DNS Infrastructure

There is more value to using the DNS infrastructure for storing and retrieving contact service information than simply mapping from one global namespace (E.164) to another (DNS) and storing data in structured DNS resource records. An obvious benefit is the fact that the DNS infrastructure is already deployed, and it has demonstrated its stability and ability scale to the needs of the Internet. An architecturally sound reason is that the distributed nature of the DNS infrastructure aligns reasonably closely

with the locality of responsibility and management of the various forms of Internet contact services.

With the mapped telephone number translated into one domain component per digit, the flexibility of DNS delegation allows distribution of control at appropriate levels of the hierarchy. Countries can directly manage the ENUM-related DNS delegations for their own country code telephone numbers. This does not mean that all the country’s telephone numbers must be managed out of a single DNS server. Quite the contrary: Any given country may elect to delegate portions of its ENUM DNS space to other organizations (based on the existing structure of the E.164 number) and ultimately down to the level of the individual E.164 number subscriber. This is described in more detail below in the section on ENUM deployment.

The ENUM Standard

This section will build on the preceding one to give more specific detail from the ENUM standards documentation. The goal here is to give a comprehensive and accurate overview of the technology without distracting detail. Therefore, the reader is referred to the ENUM specification RFC 3761 (Faltstrom and Mealling 2004) and related standards documents to obtain a complete and authoritative understanding of how to implement or operate ENUM-related services.

Mapping System: Dynamic Delegation Discovery System

RFC 3761 defines the mapping of E.164 numbers onto domain names for the purpose of enabling the storage and look-up of contact service coordinates associated with a given telephone number. To do this, it uses an existing DNS-based mapping system: the *dynamic delegation discovery system* (DDDS), which is defined in RFC 3401 (Mealling 2002a). ENUM does not simply specify the use of a particular DNS RR type; instead, it is defined as an “application” of DDDS, which already leverages the DNS. As noted above, DDDS was developed for an entirely different application: uniform resource naming. It is designed to support any number of applications, of which ENUM is just one.

The essential purpose of DDDS is to start from a string defined by an application and successively retrieve and apply transformation rules until a terminating rule is reached and the final location information is determined. This process is called *resolution*. The first string is defined by the application and is the *application unique string*.

DDDS is dynamic in that the transformation rules are stored in the network. They can be updated as appropriate at any time by entities that are authorized to maintain them. This means they may change between users’ retrieval actions, but that eventuality is managed by appropriate implementation of the DDDS algorithm—that is, client software should expect such changes to occur. The DDDS specification provides a specification for the one currently existing DDDS implementation, which uses the domain name system.

In this case, ENUM is the DDDS application and the application unique string is a fully qualified E.164 number minus any nondigit characters except for the plus

sign (+) character that appears at the beginning of the number. For example, the E.164 number could start out as +44-116-496-0348. To ensure there is no ambiguity in transcribing numbers, all other E.164-related syntactic elements such as “-” are removed and all nondigits except for “+” are removed, yielding +441164960348.

To use this application unique string within DNS, the following process takes place:

1. The “+” is dropped:

441164960348

2. A “.” is placed between each digit:

4.4.1.1.6.4.9.6.0.3.4.8

3. The string is reversed:

8.4.3.0.6.9.4.6.1.1.4.4

4. Finally, “.e164.arpa.” is appended:

8.4.3.0.6.9.4.6.1.1.4.4.e164.arpa.

This yields a fully qualified domain name, which is the key that is used for the series of DNS look-ups required to obtain the contact service references stored for the telephone number.

ENUM's Use of DNS Resource Records

To appreciate the breadth and depth of the possible deployment uses of ENUM, it is necessary to understand some of the details of ENUM's use of DNS NAPTR records and the ENUM resolution algorithm.

Once the key has been obtained as outlined above, the first step in ENUM resolution is to retrieve all available NAPTR resource records (Mealling 2002b) for that key. Those NAPTR RRs contain information pertaining to all ENUM-related services associated with that E.164 number. The information contained in the NAPTR records may provide the contact service information directly in the form of a URI or it may provide direction for subsequent DNS look-ups or other actions.

It should be clear that there may be several NAPTR records available for the key, and the ENUM client must review them to find the applicable next step. This is done by sorting the NAPTR RRs, selecting the preferred RR that matches for the desired target service, and determining the appropriate next action based on the RR's contents.

Sorting the NAPTR RRs. NAPTR RRs have an ORDER field that is used to sort the NAPTR RRs into the sequence intended by the DNS administrator for the service because the DNS itself does not guarantee any particular delivery order of result records. ENUM clients are required to review NAPTR records in this order. Note that two or more records may have the same value for ORDER; that means that any of the records are equally applicable and the client will select the most appropriate for its needs (if any).

Selecting the Preferred RR. Three fields of the NAPTR records are used for distinguishing which records are applicable for defining the client's next steps: REGEXP or REPLACEMENT (exactly one can have a value in any given NAPTR RR), SERVICE, and PREFERENCE.

If the REGEXP field is not empty, it contains a POSIX regular expression that, if it matches the key, derives from it the string to be used for the next step. If the regular expression is applied to the key and no match is made, then the next NAPTR RR of the same order is considered. In practice, most ENUM regular expressions are complete rewrites of the key (i.e., they match any input string).

If the REPLACEMENT field is not empty, then it is considered an automatic “match” for the key in this part of the ENUM processing.

Once the client has a NAPTR RR for which the REGEXP matches or there is a REPLACEMENT value, then the SERVICE and PREFERENCE fields are to be considered.

The SERVICE field includes a list of NAPTR service descriptors. For ENUM, these begin with “E2U” and may contain any number of “+<enumservice>” descriptors. The <enumservice> descriptor might in turn consist of a service and subservice, separated with a colon. For example, <enumservice> could be “SIP,” “PRES,” or any of the other IANA-registered ENUM services. An ENUM client will be looking for NAPTR RRs containing one or more specific ENUM services of interest and expects to find them here. If not, the next record is considered until all possibilities have been exhausted.

The PREFERENCE field indicates which NAPTR record includes the information for the services the registrant would prefer the client to use (in order). Unlike the ORDER field, the ENUM client is permitted to use this as guidance only and override the PREFERENCE ordering at its discretion.

Using these fields, it is the ENUM client's responsibility to find a record for which the REGEXP matches the key (or there is a REPLACEMENT value), and the SERVICE field contains the token for the ENUM service the client is seeking. The client starts with all the NAPTR records at the lowest ORDER and reviews them to find an applicable record. Only if no applicable record at a given ORDER is found does the client proceed to review all of the records at the next ORDER.

Determining the Next Action. Assuming it has found an applicable NAPTR RR, the ENUM client's next action is governed by the value of the FLAG field in the selected NAPTR record as well as by the result of applying the REGEXP to the key or using the value in the REPLACEMENT field for the new key (transformed key).

At this time, only one flag is defined for ENUM, so the FLAG field can have one of two possible states: It may be empty or it may have the value “U.”

If the FLAG field has the value “U,” then the NAPTR RR is considered “terminal”; this represents the termination of the DDDS processing for the ENUM look-up. The NAPTR RR must include a REGEXP, not a REPLACEMENT value, because the REPLACEMENT field must contain fully qualified domain names and thus cannot include a URI. The point of the “U” flag is that the

transformed key is a URI for the service indicated in the SERVICE field, and this result is the final output of the ENUM resolution.

If the FLAG field is empty, then the NAPTR RR is called *nonterminal*, and, per the DDDS algorithm, the transformed key is used to do another NAPTR lookup, and the whole process begins again. Note that any REGEXP in this next round is applied again to the original, not the transformed, key.

Theory and Practice. By far the most common current practice is to have a single NAPTR RR set look-up that yields terminal NAPTR records (with “U” flags and REGEXPs).

There is discussion of the best application of the use of nonterminal NAPTR records, and whether they should be allowed in ENUM deployments. This chapter takes no particular stand on that issue, but, where applicable, describes how nonterminal NAPTR records would be used in ways that are consistent with the ENUM and DDDS published standards.

Target Contact Services

To achieve maximum flexibility for use and future evolution, the ENUM specification itself does not enumerate the set of contact services that can be located using ENUM resolution. Instead, there is a standard process for defining such services and the necessary tokens for the ENUM standard. These definitions and tokens are registered with the IANA.

These services are defined and registered to ensure uniqueness, allowing the creation of interoperable clients and resolution services. ENUM defines these services in terms of *type* and *subtype*. Any given type may have several subtypes; together they uniquely identify a particular service.

The definition of the ENUM service type (and subtype) includes the intended function of the service and the expected URI schemes to be included as the target for the service. Although it is reasonable to expect an ENUM service type SIP to use the “sip:” URI scheme, there is no inherent requirement that the URI scheme name match the ENUM service type. For example, the ENUM SMS service type allows the “mailto:” URI scheme. Any given type may have a number of subtypes registered for it.

Example ENUM Service: SIP

The ENUM SIP service registration is contained in RFC 3764 (Peterson 2004). URIs in NAPTR records advertising this service are expected to be of the “sip:” or “sips:” scheme.

Clearly, the intention of this ENUM service is to provide mapping from a traditional telephone number to some SIP voice over IP or other media service. It is important to note that RFC 3764 specifically indicates that any URIs registered in NAPTR records for this service should include SIP “address of record” URIs as opposed to any general SIP contact URIs. The intention here is to use ENUM to find the “logical” address of the service and continue to use SIP’s more refined capabilities for determining the current contact address of the targeted party.

Example ENUM Service: Web

RFC 4002 (Brandner et al. 2005) defines the ENUM service “web” with two subtypes: “http” and “https.” The respective URI schemes associated with the types are “http:” and “https:”.

The purpose of this ENUM service is to indicate that the resource identified by the associated URI scheme is capable of being a source of information. Ultimately, connecting to the resource may yield a descriptive document, or it may launch some other form of interactive service. The “web” service definition is intentionally vague on that point, leaving much to the discretion of implementers and system developers.

Current Registered ENUM Services

The list of validly registered ENUM services is maintained and updated by IANA, based on specifications developed within the IETF (per the process defined in RFC 3761).

Table 1 enumerates some of the services that are registered at the time of this writing; see Internet Assigned Numbers Authority (2004) for the complete and official list of registered services.

Practical Examples

Following from the illustrations above, an entry for +44 1632960083 offering both “sip” and “web” ENUM services might have the following NAPTR DNS RR set:

```
$ORIGIN 3.8.0.0.6.9.2.3.6.1.4.4.e164.arpa.  
NAPTR 100 100 "u" "E2U+sip" "!^.*$!sip:  
frontdoor@example.com!"  
NAPTR 100 102 "u" "E2U+web:http"  
"!^.*$!http://www.example.com!"
```

Table 1: A Sampling of IANA-Registered ENUM Services

Type	Subtype	URI scheme
H323		h323:
SIP		sip:, sips:
IFAX	mailto	mailto:
PRES		pres:
WEB	http	http:
WEB	https	https:
FT	ftp	ftp:
EMAIL	mailto	mailto:
FAX	tel	tel:
SMS	tel	tel:
SMS	mailto	mailto:
VPIM	mailto	mailto:
VPIM	ldap	ldap:
VOICE	tel	tel:

This NAPTR RR set indicates:

- equal ordering among the NAPTR RRs (“100”), so all must be considered;
- “sip” ENUM service is provided at the SIP address `frontdoor@example.com`;
- “web” ENUM service is provided at `http://www.example.com`; and
- both of these NAPTR RRs have the “u” flag, and therefore these are terminal look-ups (there are no further steps in the resolution).

Note that the regular expression will always match the key: It matches every character in the key string (“`^.*$`”), so it is always successful.

There is some concern that an E.164 number with many contact services and highly refined expression of preference between services would have a NAPTR RR set that was too large (for a standard DNS response). There are no agreed-on solutions for this potential situation as yet, but one approach that illustrates the potential extended use of DNS here is as follows:

```
$ORIGIN 3.8.0.0.6.9.2.3.6.1.4.4.e164.arpa.
NAPTR 100 100 "" "E2U+sip" "!^.*$!sip.enum.
example.com.!"
NAPTR 100 102 "" "E2U+web:http" "" web.
enum.example.com.
```

Note that the flag field is empty—meaning that this is not a terminal look-up. If the first record matches (i.e., the client is looking for the “E2U+sip” service), then the regular expression provides the replacement that is used to look up another NAPTR RR set. Because the regular expression matches any key and uses none of it in the rewrite, it is clear the transformed key is “`sip.enum.example.com.`” If the second record matches, then the REPLACEMENT field value provides the transformed key: “`web.enum.example.com.`”

That NAPTR RR set can then be used to provide the refined level of preference expression. For example,

```
$ORIGIN sip.enum.example.com.
NAPTR 100 100 "u" "E2U+sip" "!^.*$!sip:
frontdoor@example.com!"
NAPTR 100 101 "u" "E2U+sip" "!^.*$!sip:
sidedoor@example.com!"
NAPTR 100 103 "u" "E2U+sip" "!^.*$!sip:
backdoor@example.com!"
```

Note that these are all terminal look-ups.

Putting It All Together

This section started with a discussion of requirements and then described the technology that has been developed to meet those requirements and expectations. These pieces fit together as follows.

Software Accessibility: The ENUM standard defines a technology that is based on providing structured DNS

queries and responses; as such, it is fully software-accessible.

Public Use: By its nature, the DNS infrastructure is publicly accessible. As part of the design choices, however, the only data that are stored in the DNS pertain to contact services the end user wishes to advertise for use (as opposed to requiring the exposure of personally identifying data such as name or address).

Contact Look-Up but Not Updating: DNS is uniquely a look-up protocol. There are tools and systems that have been built up to support the *provisioning*, or management, of DNS data, and they can equally be employed for ENUM-related DNS data.

Global Identifier: The E.164 telephone number is the identifier chosen for ENUM. By definition and design, it is global in scope.

Global Accessibility: ENUM makes use of the existing global DNS infrastructure. For the Internet to work, DNS name servers must be globally accessible, providing consistent answers from and to all parts of the network.

Dynamic Data: ENUM stores the contact service identifiers within the DNS resource records that are associated with E.164 numbers. If contact service particulars change for a given E.164 number, then the DNS resource record is deleted or modified as appropriate. This is transparent to users of ENUM: The DNS always provides the contact service identifiers that are available at the time of look-up.

Distributed Management: The DNS infrastructure is highly distributed. A primary concept of DNS is that of *delegations*, or allowing different entities to be responsible for separate parts of the hierarchical tree. The sections below, describing ENUM’s deployment, provide more detail on how ENUM makes extensive use of DNS delegation.

Unconstrained Contact Services: ENUM’s only requirement for contact services is that it is possible to represent them by some form of URI scheme. New URI schemes are being developed regularly, so this is not a closed set of communication service types.

Security Issues

The sections above describe how ENUM does or should work. However, no technology is perfectly resistant to attack from sources that are intent on breaking systems or bending them to their own purposes. The security issues of ENUM are well elaborated in RFC 3761. This section simply describes the key classes of potential security issues and mitigating strategies.

DNS-Specific Security Issues

In its current form, DNS is a completely open protocol, and it has long been known that there is the potential for many forms of attack to be launched against DNS servers and unsuspecting clients. For this reason, *domain name system security protocol* (DNSSEC) has been developed (Arends et al. 2005).

Irrespective of the form of the attack—for example, “man in the middle” packet interception attacks or cache poisoning—the biggest concern is whether the data the client receives for its DNS query is, in fact, authentic.

For example, in ENUM, are the NAPTR records retrieved for a given E.164 number the actual ones the end user registered? Or are they forgeries, pointing the ENUM client to connect to bogus SIP, e-mail, or other contact services?

DNSSEC is designed to address such issues by providing the means to sign and therefore authenticate DNS responses. By carrying out proper authentication of the data, the ENUM client can be assured that the DNS data retrieved are, in fact, the data the E.164 number's name server intended to provide.

As noted above, DNSSEC was developed to address many of these issues (for DNS generally, not just for ENUM). Unfortunately, deployment of DNSSEC is proceeding more slowly than recognition of the problems, and this is likely to remain an operational concern for some time to come.

Note also that DNSSEC can only ensure that the DNS data that are retrieved are what was intended.

Potential Security Issues Related to Contact Services

Even if the ENUM client can authenticate the results from the DNS query—and therefore have confidence that the correct contact service URIs have been retrieved—bad actors may still prevent the ENUM client from connecting to the desired communications service.

The process of resolving target URIs and connecting to a remote server is also potentially subject to attack. The ENUM standard requires that individual URI schemes registered for ENUM services elaborate any appropriate means for mitigating security threats. If the application protocol associated with the URI scheme supports some form of (server) authentication, then it is important to use it.

DEPLOYMENT

Having completed the discussion of the theory of ENUM—what it is trying to achieve and how the technology is designed—it is now time to review how ENUM can and does work in practice.

There are three key components to deploying ENUM:

1. the clients who build software that makes use of the data in the infrastructure;
2. the infrastructure, which establishes the authoritative registry of E.164 numbers mapped to DNS entries; and
3. data maintenance, or creating and managing the DNS resources for each number.

All three components must be functional, at least to some degree, before ENUM can be said to be deployed and useful. To a certain extent, there is a chicken-and-egg situation: Without populated infrastructure, there is no motivation to build clients; without clients, there is no motivation to populate the infrastructure.

The rest of this section will review these components in greater detail, discussing the general requirements for each and describing what exists today.

ENUM and the End User: ENUM Clients

One immediate measure of the success of ENUM is its utility to end users: It succeeds in solving the contact information problem if people can use it to advertise their contact services and make contact with other people. The last few sections have outlined the technology for how ENUM supports that. The question remains: “How do I, as an end user, access that information?”

The general assumption that drove the design of ENUM is that support for ENUM would be absorbed into a variety of communications-supporting software. This is happening in certain instances, although there is not yet a single general approach to using ENUM. Examples of what has been done so far are detailed below.

Software Using ENUM

The most obvious way to use ENUM is to incorporate its use directly into some or all forms of communication software. This software might be used directly by a user or it might be some software acting on behalf of a user to effect a communication link.

“Softphones” are software programs with telephone functionality. Notably, SIP softphones use the SIP protocol to establish voice calls. It is natural to expect that softphones would incorporate ENUM functions directly, so that the best connection can be made for any telephone number entered into the softphone. One softphone that supports ENUM today is the ENUM RTC phone, available from <http://www.enum.at/index.php?id=softphone>

However, not only client software might make use of ENUM but also various forms of server software. For example, SIP proxy servers might take a phone number from a client softphone and use ENUM to look for an appropriate SIP connection (rather than routing immediately to the public switched telephone network). For instance, the *SIP express router* (SER) server software has an ENUM module that will incorporate ENUM lookup functionality into the SER server.

Direct Lookup of ENUM Data

Another approach to making use of ENUM is to use a specialized client or a Web browser to look it up directly.

For example, the Japan Registry Service developed a software client that will allow a user to perform ENUM look-ups (see <http://jprs.co.jp/enum/software/software.html>).

This can also be achieved using special-purpose Web sites that are portals to ENUM and provide look-up services. For example, <http://enum.nic.at/> provides the ability to enter a phone number and find the ENUM results in the Austrian ENUM service.

Also, http://www.enum-trial.de/index_frame_ie.html provides a German portal to look up ENUM resources: For an E.164 number (directly or mapped into an ENUM key), it will provide contents of available NAPTR and other DNS resource records for the ENUM key.

More directly, because it is now common to use the Web browser bar to do all manner of search, there are browser plug-ins that enable ENUM lookups. For example, the ENUMapper plug-in for Firefox (available from <http://falb.at/enum4firefox/ennumapper-0.1.0.xpi>) allows a user

to enter a string such as “enum:+441632960083” in the Web browser and see the result of the ENUM look-up.

Command-Line Tools

Of course, it is always possible to look up ENUM information from a computer’s command-line interface, making use of a standard DNS look-up tool. For example, it is possible to look up all of the NAPTR records associated with a telephone number by doing the ENUM mapping to the domain name and using a tool like “host” to query the DNS.

For example,

```
host -t NAPTR 3.8.0.0.6.9.2.3.6.1.4.4.
e164.arpa.
```

might yield something like:

```
3.8.0.0.6.9.2.3.6.1.4.4.e164.arpa NAPTR 100
10 "u" "E2U+sip" "!^.*$!sip:custserv@
example.net!"
```

This is hardly expected to be the widespread access method for ENUM, but it is useful for debugging and potentially for writing basic scripts.

Building More ENUM-Enabled Tools

If none of the above tools is sufficient, then it is always possible to develop new software to make use of ENUM. This can be done using standard DNS libraries and implementing the ENUM DDDS application directly. Software development kits also have been made available to facilitate the creation of new ENUM software (or for retrofitting ENUM capability into existing software). For example, see <http://jprs.co.jp/enum/software/software.html>.

Is Anybody Out There? ENUM Infrastructure

Before it is possible to look anything up using any of the tools and techniques mentioned above, there must be populated ENUM infrastructure. Although ENUM is defined to provide services to and for the telephone number end user, it is designed to leverage the distributed nature of the DNS by following the hierarchy of the telephone number assignment established with E.164. Therefore, individual E.164 numbers are not registered directly into a centrally managed database; instead, each country must establish its ENUM infrastructure, and end-user ENUM resources can be managed within the national context and available services.

There are four general classes of ENUM DNS infrastructure to review: (1) the root of the end-user ENUM DNS, (2) per-country code registries, (3) within-country ENUM providers, and (4) within-country code registrars. These are described in more detail below.

The Root of All ENUM: e164.arpa

To provide a stable point of reference for ENUM resolution, the ENUM standard defines an authoritative root of the ENUM DNS hierarchy in which individual country codes are registered: e164.arpa. This is often referred to as “tier 0” of ENUM.

This is a key point at which the DNS infrastructure for ENUM is aligned with the administration of E.164 numbers. As part of the IETF ENUM standard, the Internet Architecture Board has established instructions to ensure that the ITU-T TSB authenticates each request for registration of country codes in e164.arpa. This, in turn, ensures that the roles and responsibilities for ENUM E.164-based DNS is aligned with those for E.164 numbers.

In terms of DNS, an approved request is implemented by inserting *name server* (NS) records for the appropriate subzone of e164.arpa for each registered country code to direct queries to the services established by its national administrator.

For example, the current registration for country code 49 (Germany) is as follows:

```
host -t NS 9.4.e164.arpa.
9.4.e164.arpa name server enum3.denic.de.
9.4.e164.arpa name server enum1.denic.de.
9.4.e164.arpa name server enum2.denic.de.
```

Note that, if no request has been made or a request has been made but not authenticated, then there will be no DNS resource records for that country code in e164.arpa., and no telephone number within that country code can make use of ENUM.

Table 2 shows the country codes that have been registered at the time of this writing. See RIPE NCC (undated) for current information.

Country Code Registries

Before making a request to register a country code, the administrator of the E.164 numbers of that country code must establish policies and infrastructure to support ENUM. While remaining consistent with implementing ENUM per the standard, the final form of infrastructure can vary from one country code to another, depending on regional requirements. In all cases, provision must be made to register the country code’s telephone numbers in DNS. The country code registry is often referred to as “tier 1” of ENUM service.

In principle, the ENUM DNS infrastructure for a given country code could be constructed to directly contain the NAPTR records for all of the country code’s E.164 numbers (this is called the “thick tier 1” model). However, that works against the purpose of DNS architecture and established administration best practices. It creates a great separation between the entity with the operational data for each domain (E.164 number) and the administration of the DNS. In addition, it would either constrain the ability to have dynamic ENUM updates or create a DNS zone that was in a constant state of flux.

Instead, more DNS delegations are usually made (“thin tier 1” model). This is done by inserting appropriate NS records along the lines of hierarchy within the E.164 number. In country codes that have explicit area codes, each area code could be delegated to other DNS servers. Commonly, though, the country code’s ENUM DNS server simply holds the NS records for each registered E.164 number.

Table 2: Current Country Code Registrations Approved for Delegations in e164.arpa

Country code	Delegee, country	Date of ITU TSB approval (dd-mm-yyy)
+1	CC1 ENUM LLC, shared country code	15-02-2006
+30	Hellenic Telecommunications and Post Commission (EETT)	06-02-2006

The country code's set policies must further define the conditions under which E.164 numbers are added to the registry or otherwise modified.

ENUM Providers

As the country code's ENUM registry does not contain the NAPTR records for each E.164 number, there must

be DNS servers to which the NS records in the registry refer to complete the DNS resolution of each ENUM domain. These are operated by organizations generically referred to as "ENUM [service] providers," or "tier 2" of ENUM.

ENUM providers' DNS servers offer the current set of NAPTR records for each E.164 number.

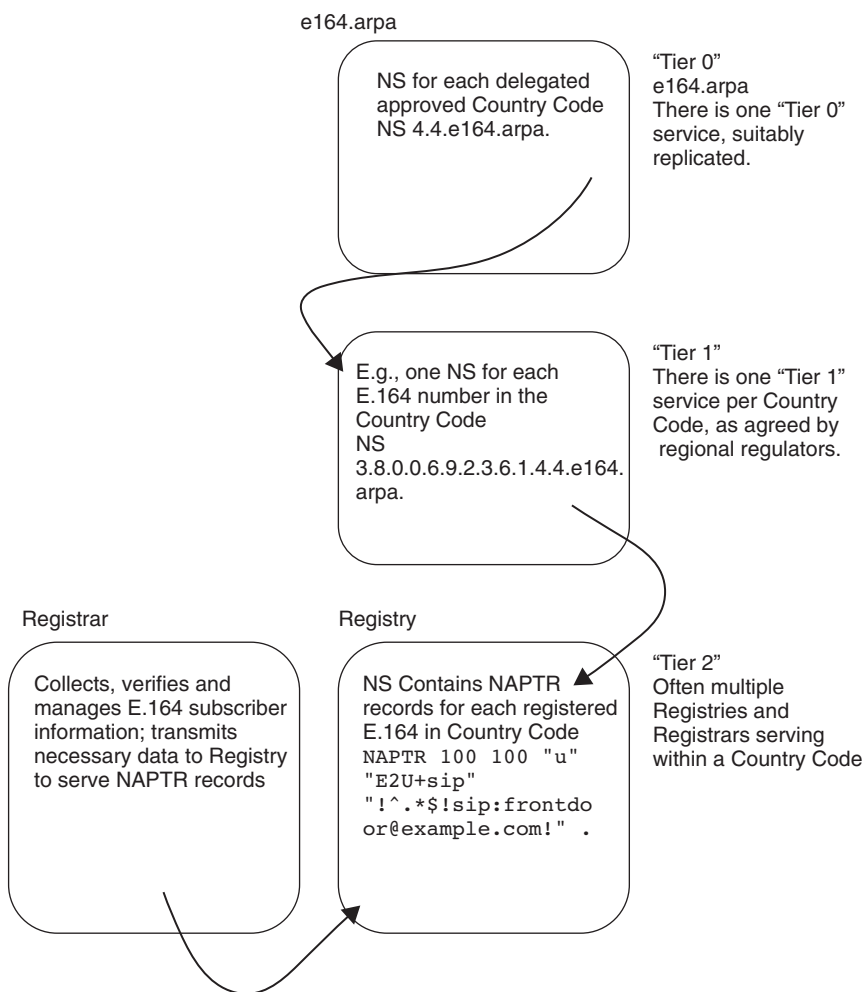

Figure 4: A view of one possible flow for distributing the tiers of ENUM DNS data management

ENUM Registrars

The registry and ENUM providers above provide the operational support for ENUM resolution. However, for ENUM to work for end users, a user-facing component of infrastructure is required. "Registrars" carry out the work of managing the creation, modification, and deletion of entries in the registry. The registrars' duties generally include the following data management duties.

Collection: Registrars work directly with E.164 end users and collect the current information about the end user's ENUM provider (for the NS record in the registry) as well as available contact service information and any other information about the registration required by the country code's established policies.

Verification: Registrars work to verify the authenticity of registration requests. Minimally, it must be clear that the request is coming from an entity that has current appropriate authority for the E.164 number (i.e., the current end user).

Publishing: NS records for verified requests must be put into the country code's registry. The registry must also be updated in the case of modifications to the data or deletion if ENUM support for the E.164 number is withdrawn.

Related data: The country code's policies will indicate what other information the registrar must gather and

retain from each request. For example, it is general practice to maintain address information for DNS registration contacts, and these include DNS entries for ENUM.

The details of information gathered, relationships with the country code's ENUM registry, and ENUM service providers, as well as other organizations responsible for the administration of E.164 numbers within the country code do vary significantly from region to region.

Pictorially

As noted above, specific choices for balancing responsibility and organization of DNS administration for ENUM may vary from region to region based on the decisions of local regulators and service providers. Figure 4 shows one possible implementation. The illustration is intentionally simplified to reduce clutter; refer to the preceding paragraphs for further detail.

End-User Data in End-User ENUM

Of course, for there to be ENUM results for those clients to retrieve, there must be data stored and maintained in the ENUM infrastructure. The ENUM standard is directed specifically at end users—that is, it is end users who have the right and responsibility to make their contact information available (or not) using ENUM.

The European Telecommunications Standards Institute has published a technical specification on “ENUM administration in Europe” (TS 102 051) (European Telecommunications Standards Institute 2002), and it includes the following for end user registration:

1. ENUM users shall be able to choose the ENUM tier 2 nameserver provider and ENUM registrar they want to use for a given E.164 number.
2. ENUM users may decide to delegate the provisioning and management of NAPTR RRs to a third party (e.g., ASP).
3. The choice of application service provider for a given ENUM-based application shall not be constrained by the choice of ENUM registrar or ENUM tier 2 nameserver provider.
4. ENUM users have the right to decide whether their assigned E.164 numbers are inserted or withdrawn within the ENUM database.
5. ENUM users have full control over the provision and content of the NAPTR resource records in the ENUM tier 2 nameserver.

In practice, this means that everything begins and ends with end users’ choices to register one or more of their E.164 numbers in the ENUM infrastructure. For each E.164, end users choose to make available in ENUM, they must

- identify contact services to be included in their ENUM registration of the E.164 number (e.g., which SIP addresses, Web sites, etc.);
- ensure those contact services are operational, whether the end user is providing them directly or obtaining the service from some other entity;
- select and establish a relationship with an ENUM provider to create and serve the appropriate NAPTR RRs for those contact services from the ENUM provider’s nameserver; and
- contact an ENUM registrar to request that the E.164 number be appropriately registered in the ENUM registry (i.e., have DNS NS records point to the selected ENUM provider).

The ENUM registrar then has the responsibilities outlined above, with respect to verifying and publishing the DNS data.

If end users wish to withdraw E.164 numbers from the ENUM infrastructure, they must contact their registrars. For any changes related to changing information about contact service information, priorities, or other data in the NAPTR RRs, end users will work with their ENUM providers.

RELATED TOPICS AND FUTURE DIRECTIONS

The previous sections have outlined the ENUM standard and technology in some depth. Of course, end user ENUM does not exist in a vacuum. This section provides

a taste of other related topics with a view to inspiring the reader to continue the exploration of this topic.

Related Topics

Managing ENUM Entries

As noted earlier, the ENUM standard is focused on providing a look-up service, not specifying updates. However, this is generally true of the DNS, and the *extensible provisioning protocol* (EPP) was defined to provide a standard registry-registrar communications protocol for generic domain name registration processes. EPP is XML-based, and intentionally extensible.

An extension of EPP has been specified in RFC 4114 (Hollenbeck 2005) to accommodate ENUM services: the specification of content for NAPTR resource records, as well as the required service interactions to create, delete, renew registrations, and so on.

Information about ENUM Registrants

Another carryover from general DNS infrastructure management is the desire to have accessible information about the registrants of the ENUM (DNS) entries. Generally, this has been useful for contacting operators and owners of DNS services in the case of network issues or other operational problems.

The IETF defined an XML-based protocol for providing access to registry information—IRIS (RFC 3981) (Newton and Sanz 2005)—and there is an IRIS service, EREG, that is specifically designed for ENUM defined in RFC 4414 (Newton 2006). EREG provides the capability of storing registrant information particular to ENUM in a standardized service while providing managed access to that information, encryption, and authentication.

Privacy

As ENUM development and deployment as advanced, concerns about privacy have been voiced. Although privacy was not originally a driving requirement for the development of ENUM, there have been discussions about the implications of exposing (personal) data in the global DNS and the infrastructure systems that have been built to support ENUM.

At the level of basic ENUM technology, it must be recognized that the purpose of ENUM was to provide global, unbiased access to mapping telephone numbers to contact coordinates. Therefore, the only way to ensure that personally sensitive information is not available through ENUM resolution is “simply” not to store it in the NAPTR records associated with one’s telephone number. “Simple” gets a little more complex when considering the technological and regulatory aspects.

Most of the contact service types supported by ENUM provide some means of “aliasing” contact addresses. Therefore, it is not necessary to store a personal e-mail address in a NAPTR record; one could instead list an anonymized alias and configure that alias’s service to forward any received mail to one’s personal account. Some contact services also provide end-user control over connections. For example, one can publish SIP address in a NAPTR record and still only accept connections from known

callers. That places the burden of filtering unwanted communications on the communication technology itself.

On the regulatory front, as countries establish ENUM services in trial or deployment form, much care and consideration has gone into determining the right balance of providing a uniform service (all telephone number subscribers) while protecting personal privacy rights. Most people favor a balance that ensures that no subscriber is required to participate, and all subscribers have control over the contact service information that is (or is not) stored in NAPTR records associated with their telephone numbers.

The Future: Beyond End-User ENUM

This chapter has focused on ENUM as originally designed for the use of individual telephone subscribers, or end users. There have been many discussions about other possible uses and extensions of ENUM for other purposes—for example, within enterprises or between telephony networks.

One such proposal is for an “infrastructure” or “carrier” ENUM to facilitate the interconnection of networks providing E.164 number services. The purpose would be to provide a means for the E.164 number’s “carrier of record” to advertise its point of connection for (voice over IP) services for that number. The important difference between this and the end-user ENUM described in this chapter is that the carrier ENUM registrations would be managed by and for the carrier and its services, as opposed to holding the URIs that end users specifically designate as their specific points of contact.

Nothing is yet standardized within the IETF’s ENUM Working Group, and discussions continue to evaluate the merits of the overall proposal.

CONCLUSION

This chapter has provided a brief tour of ENUM from inception through current deployment reality and directions for growth. The designers of ENUM set out to provide easy access to several communications technologies by providing a robust, dynamic, and distributed system that associates contact service information with existing telephone numbers. ENUM is being actively deployed, as is witnessed by the number of E.164 country codes that have been registered and for which operational services are available. The story is not finished; more services will be defined to use and support ENUM, and new directions are still unfolding within the IETF’s ENUM Working Group.

GLOSSARY

Dynamic Delegation Discovery System (DDDS): A generic framework for managing mapping and discovery services across the global Internet.

E.164 Number: The ITU-defined standard for global telephone numbers.

International Telecommunications Union (ITU): The international organization within the United Nations system where governments and the private sector coordinate global telecom networks and services.

Internet Engineering Task Force (IETF): The organization responsible for the creation and maintenance of standards that define many of the core protocols of the Internet, including the ENUM standard.

Naming Authority Pointer (NAPTR): A particular DNS resource record type defined for use in DDDS applications.

Session Initiation Protocol (SIP): An IETF-defined protocol for IP-based media services, including Voice over IP.

Voice over Internet Protocol (VoIP): A general class of applications that carry voice communications over the Internet rather than through traditional telephony networks.

INTRODUCTION

Web hosting is an arrangement by which a company that specializes in the ongoing management of the technology and resources to run a Web site provides such a service for another company, organization, or individual. A typical Web hosting provider offers such services for many clients. Web hosting is not about the *creation* of an organization's Web site; it is about taking an organization's Web site and placing it on one or more servers, making it available on the Internet, and maintaining the Web site's operations on behalf of the client organization.

Web hosting is a rapidly growing and changing area. Hosting service providers and the types of services they offer change week by week and month by month. Likewise, the platforms and specific software employed are also subject to rapid change. With this in mind, the goal of this chapter is to focus on the technical aspects of Web hosting, seeking the conceptual core that will persist even amongst the constant change that we must expect to continue.

The subject of Web hosting must be viewed from two perspectives—the perspective of the provider and the perspective of the client. From the perspective of the client, Web hosting is about the business decision to outsource the day-to-day operational concerns of running their Web site and the technical issues that must be considered in making such a decision. The client must also decide what service components they require from the provider among a myriad of choices. From the perspective of the provider, Web hosting involves the integration and composition of many of the networking topics addressed in other chapters of this book. Web hosting is a vertical slice from the network stack, and the provider must select from alternatives at each level, resulting in a large number of possible combinations.

In the remainder of this introduction, the client perspective will be discussed as we explore the central idea of outsourcing and its advantages and disadvantages. We then describe in the section entitled “Provider Models”

each of the provider service models that predominate in the industry. This is in part a client perspective and in part a provider perspective. The models section continues by differentiating the provider models of Web hosting from those of application service providers. In the section entitled “Architectural Issues,” we introduce the service component hierarchy, allowing an integration of the provider models. The issue of fault tolerance, which has aspects in all of the levels of the service component hierarchy, is also introduced. The service component hierarchy will serve as a framework for the rest of the chapter, in which it will be used as a vehicle to discuss the various network issues and decisions that form the technical basis of Web hosting in the section entitled “Physical Infrastructure,” the section entitled “Network Connectivity and DNS,” and the section entitled “Web Site Architectures.” The presentation will also serve to relate the service components back to the provider models.

Outsourcing is the decision to contract services with an external company instead of providing those services within an organization. In the case of Web hosting, this refers to the outsourcing of information technology (IT) expertise, Internet connectivity, data center operation, domain name service management, Web servers, and affiliated software for the operation of the organization's Web site.

Two issues are core to the genesis of the rapidly growing Web hosting industry. First, for almost every business, large or small, and almost every organization, large or small, the presence of the organization on the Web has become a mandatory and critical element. Second, and corollary to the first, there has been a transition in the types of organizations with a Web presence. In the early days of the Web, the organizations with a Web presence were dominated by high-tech companies and research organizations, wherein networking and computer services were a core competency. As the Web has evolved into the primary face of marketing for any type of business, the domain of expertise has shifted, and it is now

the exception that networking and computer services are a core competency of the organization.

Given these two central issues, the advantages of outsourcing Web hosting can be summarized into the areas of competency, reliability, time, and cost.

- **Competency:** Web hosting providers specialize in the infrastructure and networking issues that are required to operate and maintain availability of a Web site. When the domain of expertise of an organization is not aligned with this networking competency, outsourcing Web hosting allows the organization to focus on the strengths and mission of the organization.
- **Reliability:** An organization's Web site has become the "store front" by which interested parties (existing or potential customers, organization members, etc.) interact with the organization. In many respects, the Web presence becomes a proxy for the organization itself. As such, the Web site has become a business-critical resource and any lack of availability or decrease in reliability (actual or perceived) becomes costly to the organization. Web hosting providers, in addition to the networking competency, are (or should be) experts in fault tolerance and in increasing the availability and reliability of the Web sites they host.
- **Time:** Web hosting services can greatly reduce the time required to make a Web site for an organization available on the Internet. Web hosting providers have all of the infrastructure and servers already in place, along with many tools for rapid development and deployment of a Web site. Particularly for small Web sites, the site can be up and running and available on the Internet almost immediately.
- **Cost:** The issue of cost is at the heart of many of the previously cited advantages of outsourcing. The Web hosting provider can amortize all the associated costs of running a Web site, from building and supporting a data center with fault-tolerant data and control, to security, to support staff and operators on site around the clock, over many clients and Web sites. In addition to reducing the cost per client, this also serves to reduce risk among the set of clients.

The disadvantages of outsourcing the Web site operations for an organization revolve around the issues of (i) control; (ii) cost, if the outsourcing is a duplication of expertise you require in-house for other reasons; and (iii) recourse when something goes wrong. Whenever a decision is made to outsource, the organization is giving up control of the operational aspects of its Web site. This is primarily a concern when existing IT staff have made a significant investment in time and effort for current Web site operations. Likewise, if the organization is an Internet-based enterprise for which Web technologies are already a core competency, outsourcing may mean duplication of resources and expertise and thus may mean additional cost over what is already required for in-house purposes. Finally, the issue of how often things go awry with a Web hosting provider and how quickly the problem is resolved can be a disadvantage. For the client, the best protection is through contracted service level agreements

with the Web hosting provider. Since the purpose of this chapter is to detail the technical and networking issues of Web hosting, such business-level issues will not be addressed further.

Corollary to the issue of the loss of control is the issue of privacy. In Web hosting, the service provider has access to the information and raw data of the client organization, creating an inherent set of privacy concerns. The client organization must assess to what degree the provider can be trusted to protect its information.

PROVIDER MODELS

Web hosting services may be packaged and assembled in numerous ways, corresponding to the wide range of requirements different types of customers may have. Over time, the sets of services have converged to a handful of *provider models* agreed upon within the industry. A brief look at these models will allow a categorization of vendor offerings and will give a starting point from which to discuss the service component hierarchy in the third section of the chapter and then to proceed level by level up that hierarchy in the sections that follow.

COLOCATION

One of the most fundamental (and earliest) provider models is that of *colocation*. In colocation, the client is simply contracting for two things: the physical facilities in which to house their Web servers, and the Internet access required for data to and from those Web servers. The client provides its own server hardware, Web server software, and expertise for operations of its Web site. The vendor provides the data center real estate sufficient for the client's server hardware and the intra-data center networking and Internet access.

Colocation offers clients control and in-house expertise over their Web site operations. High-quality Internet data center facilities are costly, and sharing good facilities with other clients while maintaining control and/or unique configurations of a Web site is a reasonable alternative for some organizations. Also, colocation facilities may be combined with Managed Services, discussed in the section entitled "Managed Service Providers."

SHARED SERVERS

For a client organization, the least expensive entry in Web hosting is the *shared server* model. This is the predominant model in use at the present time. The use of the word *shared* refers to the fact that clients' software Web servers are, in fact, virtual, and multiple Web servers are executed on the same physical server (see Figure 1a). In this model, the provider is responsible for the Internet data center and also owns and maintains the server hardware. The client rents its portion of the physical server and publishes its Web site by transferring the Web site to the server.

The client typically has a registered domain name, and the mapping from the client's domain name (or a subdomain thereof) resolves to an IP address of the physical server. Multiple IP addresses can map to the same physical server, meaning that multiple Web sites can be

Figure 1: Shared server alternatives

supported on the same machine. Once traffic (in particular, HTML traffic) is directed to the correct machine, this becomes a function of the Web server software on the server. See the chapter entitled “Domain Name Systems,” for more information on mapping from a domain to an IP address.

Depending on a number of factors, tens to hundreds of clients may be shared on a server. The implication is that they are sharing CPU, memory, and bandwidth, as well as the operating system software and other layers of software up to the point at which traffic is split among virtual Web servers. A variant of this provider model is known as *virtual private servers*. In this variant, the server is partitioned into *virtual machines* (not virtual Web servers). As depicted in Figure 1b, each virtual machine is capable of running its own (and perhaps different) operating system along with any desired support software. Although CPU and memory are still shared, resource allocation may be tightly controlled with no single virtual machine able to usurp more than its share of resources. This also serves to build a security barrier between virtual machines and their associated clients.

Under the shared server model, it is still possible to define a Web site that utilizes database and/or interactive or scripting capabilities. This depends on the vendor and the tools and facilities that they provide. If the shared server is not a virtual private server, the set of tools are likely to be prescribed and controlled by the vendor (such as type of database and tools for interacting with the database).

An extreme point in the spectrum of shared servers is that of *free hosting* service providers. These Web hosting providers host the Web sites of client organizations, typically with many client Web sites on the same physical server. Such free hosting providers do not charge the client organization for the hosting service. The business model may realize revenue through alternative channels such as the appearance of forced advertising integrated into the client Web site, or through potential future revenue by offering management and customization when the client organization moves into a higher tier of service. This would then become a managed service provider model as discussed in the section entitled “Managed Service Providers.” Often in this free hosting arrangement, client organizations may not have their own registered domain names; instead, they have a subdivision of

the provider’s domain. This style of Web hosting is made cost effective by limiting client capabilities through prescribed templates and Web site building tools, resulting in Web sites that may be created and maintained with little human system administration.

The shared server provider model is appropriate for small to midsized Web sites.

Dedicated Servers

The *dedicated server* model, as its name implies, involves no sharing of a physical server between multiple clients. The server hardware is provided by the vendor but is under the complete control of the client, who is leasing the entire machine. The provider is also still responsible for the physical infrastructure and Internet data center. This solution offers more capacity, more flexibility, and better security. As a result, it is also a more expensive alternative.

For a single Web site on the server machine, the mapping of domain/subdomain to the IP address of the server is simplified, but it still involves appropriate domain name system (DNS) translation to the IP address on the physical server at the provider’s data center.

The dedicated server provider model is appropriate for midsized to large Web sites, and for Web sites with unique configurations and/or the need for custom software. A single client with multiple Web sites might also find this an attractive model, as it could place these Web sites onto the dedicated server.

Managed Service Providers

For organizations that require high levels of configuration and customization for their Web site but lack the in-house expertise that a dedicated server solution would require, the *managed service provider* may offer an appropriate solution. In this model, the provider is responsible for building a complete solution, including the design, configuration, and customization of the server hardware and software. In this model, the vendor often does *not* provide the physical infrastructure and Internet connectivity. This may occur independently through a colocation vendor, or a managed service provider and a colocation vendor may enter into a partnership agreement, in which the data center choice is predetermined.

Since managed service providers specialize in custom solutions, often targeted at high-end Web site requirements, the exact set of services included is difficult to pin down. Managed service providers range over a spectrum from extremely flexible providers who build very custom solutions, to those with a more rigid set of a la carte choices that they have vetted and are compatible with one another.

HYBRID AND SPECIALIZED MODELS

It should be clear from the preceding discussion that these provider models are rough categorizations, and many permutations are possible, resulting in many *hybrid models*. A managed service provider may be coupled with a colocation provider. A managed service provider may provide the configuration and customization but use a

dedicated server provider for the data center and server hardware. A vendor providing colocation services may also offer managed services that are tied to its locations.

Specialized Web hosting providers are those providers that may host a subset of their client organizations' Web site content. A popular class of specialized Web hosting provider is that of media content providers. In this example, client organizations may already maintain their own Web site, or may have a general Web hosting provider for their main Web site content, but the storage and bandwidth performance issues associated may make providing it in-house infeasible. The media content providers host just the streaming media on their streaming servers, and typically will have customized the storage and network bandwidth infrastructure to more efficiently provide this type of content.

Another type of specialization also deserves description. Instead of hosting a traditional Web site, or a subset thereof, one could host specialized content that appears in prescribed form and with a limited set of potential elements. One form of this specialization is that of *profile hosting*, such as that provided by organizations such as MySpace (Anderson 2006) or Facebook (Zuckerberg 2006). Members, profiles may be tailored and customized according to the clients' interests and share many qualities of personal Web sites. Another form of this specialization is *blog hosting*, in which the focus is the exchange and sharing of information (news, journals, photos) through Web logs (blogs). These types of specialization may also be categorized as shared server providers. In these cases, the number of individual clients hosted on a physical server may be quite large. As a consequence, the request/reply traffic to the physical server could differ substantially from a traditional Web site.

Differentiating from Application Service Providers

The purview of *application service providers* (ASPs) is the application software, such as human resource software, or software for the management of business processes. These applications are critical business elements and most often execute within a company's intranet.

Whereas many of the applications that are supported by ASPs have Web-based interfaces, this means that they require the support that Web hosting solutions provide, not that they supplant nor subsume Web hosting. ASPs are not infrastructure providers and typically do not share the same expertise as that required by Web hosting providers in designing and operating a high-quality Internet data center. Because of the complex requirements and configurations ASPs need to support the intranet applications, ASPs may often be clients of managed service providers. See the chapter entitled "Application Service Providers" for more information on ASPs.

ARCHITECTURAL ISSUES

Service Component Hierarchy

The *service component hierarchy* in Figure 2 is used to illustrate the components of Web hosting and their relationships. It is composed similarly to a network stack

Application
Web Server and Database
Operating System and Script Support
Server Hardware
Load Balancing
Support Services
Network Connectivity and DNS
Physical Infrastructure

Figure 2: Service component hierarchy

with each layer supporting the layers above it, and each layer depending on the layers below.

The three lowest levels of the service—component hierarchy—physical infrastructure, network connectivity, and support services—are services provided by colocation providers, shared server providers, and dedicated server providers. The support services level is intended to capture the need for providing backup and recovery mechanisms for client organizations as well as the ability to reboot server machines in the event of a failure. Given that many Web hosting providers have limited physical access by the client organizations, these types of remote services are commonplace. The sections entitled "Physical Infrastructure" and "Network Connectivity and DNS" will describe the lowest two levels of the service component hierarchy in detail.

Depending on the particulars of the service offerings, the next three to four levels of the service component hierarchy, namely the load balancing, server hardware, operating system and script support, and Web server and database, are provided by shared server providers, dedicated server providers, and managed services providers. These levels in aggregate define the Web site architecture, and are described together in the section entitled "Web Site Architectures." Managed service providers specialize in more variations of Web server and database configurations, whereas shared and dedicated server providers have more constrained support in these levels. The application level, and the content that is encompassed by the application level, is the responsibility of the organization or may be provided through an ASP.

Fault Tolerance

As the discussion continues in the next set of sections of this chapter, we shall repeatedly discuss the issue of fault tolerance at many of the levels of the service component hierarchy. It is worthwhile at this juncture to describe some of the common principles of fault tolerance, as we will be applying these principles throughout the remainder of the chapter.

At the heart of any fault-tolerant design, be it for physical infrastructure or for networks or for services, is the guiding principle of using redundant, failure-independent elements, so that the failure of any individual element does not cause a system-level failure. System-level failures translate into a lack of availability of services. Through the use of redundant paths and network and computing elements, and based on the assurance that these elements fail independently, the probability of a system failure is the product of the probability of the failure of the elements.

When there is no redundant path, network element, or software service, this constitutes a *single point of failure*. The probability of failure of the system is simply the probability of failure of this nonredundant element. It should also be noted from the above characterization that redundancy alone is not sufficient to get a fault-tolerant benefit. The key is that failures must be *independent*. Nonindependent failures are called *common-mode* failures and tend to be the result of elements having a common root cause for a failure.

Security

We noted in the introduction that privacy concerns must be assessed when a client organization considers outsourcing its Web site. In addition, the overall security of an organization's Web site crosses the boundaries of most of the service component hierarchy levels. This issue is not specific to Web hosting, as the same security issues must be addressed whether the Web site is hosted in-house, or is hosted by a Web hosting provider.

Physical security must be addressed in the physical infrastructure level, including limiting access to the facilities and securing the infrastructure discussed in that section. In the network connectivity level, data as transmitted between browsers and Web servers must be confidential and protected against both eavesdropping and manipulation. Encryption techniques are typically employed through the use of the HTTPS protocol and certification of servers. In the support services level, backup and recovery contribute to the security of the Web hosting solution. Above this level, within the Web site architecture, additional protection may be provided through the use of firewalls and intrusion detection systems. Furthermore, load balancing can be used to provide some protection against denial of service attacks.

Detailing all the possible security issues and their solutions is beyond the scope of the present chapter. Within Volume 3 of this handbook, the section on networking planning, control, and management dedicates a number of chapters to various security issues, including the chapters entitled "Social Engineering," "Intrusion Detection Systems," "Network Attacks," "Denial of Service Attacks," "Cryptography," and "Firewalls."

PHYSICAL INFRASTRUCTURE

At the lowest level of the service component hierarchy is the *physical infrastructure* layer. This level includes the physical plant, such as the building in which physical servers are stored; the utilities to power, air condition, and heat the facility; security to limit access to the facility; power distribution within the facility; and racks and cages used for the installation of server hardware. When the physical infrastructure is combined with the next level of network connectivity, these facilities are known as Internet data centers (IDCs).

Whether the provider model is colocation, shared server, or dedicated server, a Web host provider must design and provision a quality physical infrastructure. For a colocation provider, this, along with network connectivity and DNS (the next layer up), is the primary service provided. For shared and dedicated server providers, this

physical infrastructure is needed to assure reliability for the servers at the facility. The physical infrastructure design should encompass goals of adequate power requirements for current and anticipated growth of hosted servers, physical security, and fault tolerance.

Physical infrastructure includes the following elements:

- Building
- Electrical power (including generator or battery backup)
- Other utilities, such as natural gas and telecommunications
- Air conditioning
- Fire suppression
- Physical security
- Physical connection to the Internet service provider (ISP) of the facility
- Internal equipment racks, cabinets, or cage

Considerations for these elements can be divided into concerns from *within* the facility, and, for those with external connections, the *point of entry* of the physical infrastructure element.

Point of Entry

The physical infrastructure elements of electrical power, natural gas, telecommunications, and physical Internet connection must all originate from suppliers outside the facility and have some point of entry into the facility. Likewise, a generator providing backup electrical power may be outside the facility and require a power line entering the facility.

For all of the above, this point of entry constitutes a single point of failure, and to provide fault tolerance at the physical infrastructure level, a Web hosting provider must provision redundant points of entry for all such entering utilities. This kind of fault-tolerance design is often to guard against so-called *backhoe* failures, in which a construction-site backhoe can inadvertently cut through electrical or fiber-optic paths entering a facility. To be effective, multiple points of entry should be on opposite (and hopefully failure-independent) sides of the facility, and the paths to utilities must remain independent all the way to the source. When multiple points of entry rejoin at the next power substation or telecommunications central office, these represent common-mode failures, and the fault-tolerance benefit is lost.

Note that there is a difference between providing fault-tolerant paths for electrical power and natural gas from that of the fiber-optic bundles used for the physical Internet connection. In the former, the utilities are commodity, and one point of entry is equivalent to another. In the latter, failure independence argues for physical connection to at least two different Internet service providers. When the failure of one occurs, the network routing from anywhere on the Internet must be able to handle a change in routing through a different ISP to access the Web server addresses that will be housed in the Internet Data Center. This issue is not part of the physical infrastructure and will be addressed in the section entitled "Inter-Domain Routing."

Intra-Facility

The point-of-entry discussion implies the requirement of redundant power (including generators), natural gas, telecommunications, and physical Internet connection. Within the facility, redundancy is also required.

Air conditioning is required to keep servers, which generate a great deal of heat, from overheating, particularly when servers are packed together to maximize computing power per building square area. Data centers should provide redundant air conditioning. If a facility requires n air conditioning systems for current requirements, they should employ $n + 2$ or $n + 3$ to provide the additional redundancy.

Redundant power supply from the grid was cited earlier as a requirement, but good data centers also provide generators and battery backup. For generators, sufficient fuel should also be provisioned. For greater reliability, many modern data centers maintain contracts with separate fuel suppliers to ensure deliveries in the case of a regional natural disaster.

Another issue within the facility is the layout and utilization of space required for servers, routers, storage subsystems, and other Web site hardware components. Since colocation vendors must provide access to the staff from their client organizations, cages can be used to create individual data centers. Servers may also be configured in locked cabinets and/or standard-form racks.

A final issue for the physical infrastructure layer is that of physical security. The Web host provider must limit access to the data center and may incorporate alarm and locking systems and biometric security devices. This becomes increasingly important for colocation providers and dedicated server providers in which the IT staff of the organization may require access to the servers.

NETWORK CONNECTIVITY AND DNS

One of the most basic requirements of Web hosting is that end users, whose locations may be anywhere on the Internet, must be able to access a hosted Web site of the client organization, given a logical name. The end users are the customers, members, or general visitors of the company or organization that is responsible for the content of the site. The logical name is a fully qualified domain name, such as `www.company.com` or `www.organization.org`. This accessibility is encompassed by the term *network connectivity* and refers to the two-way flow of traffic between end users and the Web site. The translation from the logical name into the IP address(es) of the Web site is handled by the DNS. These, then, are the topics of this section.

For the purposes of this discussion, the problem is divided into three parts:

1. Inter-domain routing: routing between the IP address of an end user and the physical facility that houses the Web site.
2. Intra-domain routing: routing within the data center.
3. DNS: mapping the logical name known to the end user into an IP address. In an end user access timeline, this step would be accomplished before inter-domain routing would begin.

As a starting point, we assume that the IP address(es) involved have been allocated and assigned. Either the Web hosting provider owns its own set of IP addresses (which it may have received through its own Internet service provider) and apportions them out to the client, or the client owns its own IP addresses. A client coming in with its own IP addresses is not common, and is more likely with a colocation provider client than a dedicated or shared server provider client.

We will first discuss the two parts of the IP routing problem, assuming that the logical name of the end user maps to one of the IP addresses of the Web server. The logical name to IP address mapping is relatively independent of the routing issues, and will be discussed in the section that follows.

We have allowed that multiple IP addresses can resolve to the same physical server, both to support virtual servers in the shared server case, and to support multiple Web sites for a single client in the dedicated server case. This may be accomplished by a combination of multiple network interfaces, and by the ability to assign multiple IP addresses to a single network interface.

Inter-Domain Routing

As described in the chapters entitled “The Internet Fundamentals” and “The Internet Architecture,” the Internet is partitioned into a set of autonomous systems (ASs), which defines an area of network infrastructure under a single technical and administrative control. Every public IP address must belong to at most one AS; typically, an ISP is associated with a single AS. Most end users’ IP addresses belong to the AS of their ISP, whereas larger organizations may define their own AS, as opposed to the AS of their ISP. ASs interconnect via dedicated links and public network access points, and exchange routing reachability information through an exchange between border routers of the connected ASs using the border gateway protocol (BGP).

BGP (currently version 4) is the standard used for inter-domain routing in the Internet. The unit of routability provided by BGP is the *network prefix*, which is an aggregation of IP addresses in a contiguous block. BGP peering sessions between ASs convey to one another information about these sets of addresses that they know about, and the path through a set of ASs by which those addresses may be reached. BGP is a path vector protocol and its default routing for a given IP address is to use the shortest AS path to the network prefix that includes that specific IP address.

Suppose that an end user initiates an interaction with a target Web server at an IP address, x . Each AS will, in turn, look at the destination IP address and determine what network prefix, p , it belongs to. Through the information collected in BGP peering sessions, the current AS can determine the next-hop neighbor AS in the AS path for p , as well as the border router r that connects that next-hop neighbor AS with the current AS. The current AS will then route packets with target address x across its own AS to r , where they will proceed to the next AS.

Note that calling the role of BGP *inter-domain routing* is, in fact, a misnomer; it is really inter AS routing. This becomes

evident in Web hosting, where the Web hosting provider defines an AS that end users need to route to for access to the Web server of their organization, but the logical domains/subdomains of many organizations are within the umbrella of the single Web hosting provider AS.

We argued in the “Physical Infrastructure” section that, for reliability and fault-tolerance, an Internet data center should be connected to at least two different ISPs. When a Web hosting provider is connected to the rest of the Internet through a single ISP, there is only one BGP AS-path route to the AS of the Web hosting provider. When a Web hosting provider is connected to two different ISPs, the supporting inter-domain routing can be configured in two ways: *failover* and *multihomed*.

In a failover configuration, one of the ISP connections serves as the primary one. If no failure has occurred, *all* of the Internet traffic to and from the Web hosting provider occurs through the primary ISP. The BGP information is the same as if there were only one connection. If the connection to the primary ISP fails, a recovery action takes place and all traffic occurs through the backup ISP. The path through the backup ISP is not advertised through BGP peering exchanges until the failure occurs or exchanges effect the BGP metrics so that the backup will not be selected if the primary is viable.

In a multihomed configuration, paths through multiple ISPs are active and available for the routing of traffic to the Web hosting provider. Because of limited mechanisms for controlling BGP, this method is complex and it can be exceedingly difficult to balance the IP traffic load between the multiple ISPs. The traffic associated with a network prefix can have great variability. When configured well, however, this configuration offers the possibility of greater traffic balance in the absence of failures, and this can translate to better performance in terms of latency and jitter between an end user and the target Web site. When a failure occurs, all network prefixes of the Web hosting AS must be advertised through BGP at the surviving ISP connection.

ISP Relationships: Peering and Transit

Another issue that requires consideration when a Web hosting provider connects to multiple ISPs is the business relationship between the Web hosting provider and their ISPs (and between ISPs in general). Just as an individual can pay for Internet access through his or her ISP, a Web hosting provider or a local ISP can pay for upstream access through another ISP. This type of relationship is called *transit*, and, in exchange for the payment, the ISP guarantees to accept packets bound for any host on the Internet and to provide a return path for packets bound for the customer. At the backbone of the Internet, and sometimes at regional levels as well, ISPs (or, more precisely, ASs) may agree to exchange traffic without a corresponding payment. This is called a *peering* relationship and is generally established for the mutual benefit of two comparably sized ASs. A peering relationship will always route traffic to the transit customers of the peering partner. It may not, however, route traffic coming in from one peering partner; route within the AS, and exit the AS through *another* peering partner. This type of routing uses the resources of the AS without any corresponding revenue.

Figure 3: Peering/transit example

What this means for Web hosting is that, if the Web hosting provider has multiple ISPs and is in a peering relationship with one or more of these ISPs, there is a possibility that an end user may be precluded from accessing a hosted Web site. Consider the example depicted in Figure 3. Suppose for this example that the Web hosting provider is itself an ISP labeled A in the figure. As such, it may have a peering relationship with ISP B. Assume a Web site named *a* is hosted by this provider. Further suppose that we have two end users: end user *b* is a transit customer of ISP B, and end user *c* is a transit customer of ISP C. ISP C and ISP B may also have a peering relationship, as depicted in this example. End user *b* is guaranteed accessibility to *c* through the transit relationship with B, and, when B routes to A, A will route to the Web server at *a*. End user *c*, however, is not guaranteed accessibility. End user *c* uses transit routing to ISP C, and ISP C will use the peering relationship with ISP B to pass traffic to this next AS in line. However, since ISP A is not in a transit relationship with ISP B, ISP B has no obligation to pass traffic across its AS from C to A. So, for end user *c*, the Web site *a* may be inaccessible.

To preclude such reachability problems, a Web hosting provider should establish a transit relationship with at least two of its connecting ISPs.

Satellite Data Centers

This subsection on inter-domain routing and the connections of a Web hosting provider to multiple ISPs concludes with a matter that occurs in practice, the connectivity architecture when a Web hosting provider establishes *satellite data centers*. Satellite data centers are typically the result of the growth of a Web hosting provider beyond its current facilities, and its needs to create an additional data center in the same regional area. If a Web hosting provider has existing business relationships with two ISPs, the resultant connectivity with a satellite data center could take a number of forms. Figure 4 illustrates three basic possibilities.

In Figure 4a the existing data center and the satellite data center both have independent connections to both ISP A and ISP B. The fault tolerance of the system has not been diminished by adding the satellite data center. In Figure 4b the satellite data center is not connected to any ISP and receives all traffic through the existing data center. This link constitutes a single point of failure, and fault tolerance suffers. In Figure 4c each data center is connected to one ISP, but not to both. Here the two data

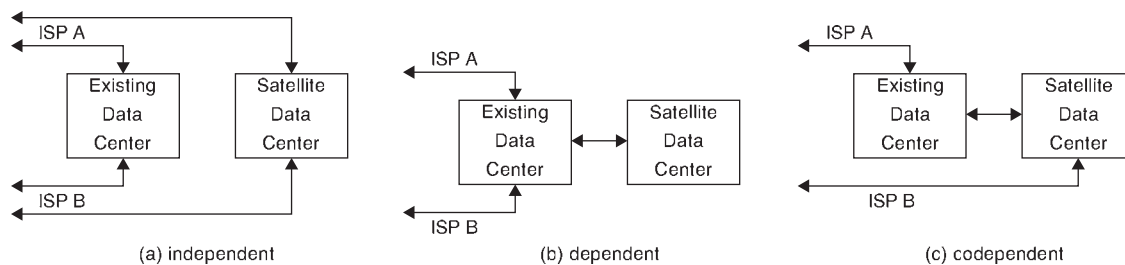

Figure 4: Satellite data center/ISP connectivity

centers are codependent, and, although there is no single point of failure, the links in the absence of failures will act in a failover mode of operation, and traffic load may not be balanced.

Intra-Domain Routing

Once traffic can be routed between end users and the AS of the Web hosting provider, traffic within the AS still needs to be routed from the border router(s) to the physical server of the Web site. Intra-domain routing protocols at the network protocol stack level define the process to determine, hop to hop, the route packets take within the AS. These protocols are described elsewhere in the chapter entitled “Network Layer Protocols.” These protocols support multiple paths between source and destination, and dynamically adapt to changing conditions, such as a path becoming inviable, perhaps due to failure.

The concern for Web hosting providers is again one of reliability. To eliminate single points of failure, the intraAS network of the Web hosting provider must include multiple paths through redundant routers between border gateways and the server hardware. These issues must be considered from the initial design of the internal network of the Web hosting provider.

DNS

With respect to Web hosting, the basic requirement of DNS is to translate a logical Web site name, such as `www.client.org`, to the IP address of the appropriate server at the data center of the Web hosting provider. In this example, the `www` is the name of the host, and `client.org` is the *second-level domain*. Together, the host part and the second-level domain part constitute a fully qualified domain name.

Recall the steps of the translation process, described more fully in the chapter entitled “Domain Name Systems.” The end user begins with a DNS query with the fully qualified domain name. This query is sent to a root name server, which returns a top-level name server. This top-level name server has translation mappings from all second-level domain names under its top level (`client.org` under `org`, in this example) to the authoritative name servers for the second-level domain. These name servers are returned through DNS to the end user, who continues by then making a query to these name servers for the requested host (`www`). The authoritative name servers for `client.org` then provide an IP address for `www` in the `client.org` second-level domain.

The issue in the context of Web hosting involve two levels of the DNS translation process and how (or by whom) the content is maintained. At the lower level, the authoritative name servers for the client organization’s second-level domain must have entries for the IP addresses of the Web site’s servers. At the higher level, whenever there is a change of second-level domain name servers for the client organization, the top-level name servers must be updated to reflect the new name servers.

Improper management of DNS entries is an extremely common source of failure preventing an end user from accessing the Web site of a client organization. As such, the Web hosting provider, for whom reliability should be paramount, has great incentive to control the second-level domain name servers. Control of the name servers also gives the Web hosting provider flexibility in making changes in physical server IP addresses. The client organization, however, also desires control of these name servers, because they also must provide mappings for all the other DNS-resolvable hosts of the client organization. These could include mail servers, internal hosts, or hosts of an extranet defined by the organization.

For shared server providers, the name servers are almost always under the control of the Web hosting provider. To allow for other (non-Web site) hosts to be resolved by the name server, the provider typically offers a *control panel* with which the client organization can add additional entries. The capabilities and level of DNS control offered by these control panels can vary widely.

For colocation and dedicated server providers, wherein the client organization is typically larger and involves more non-Web site hosts that must be managed, a common solution is for the public name servers to be owned by the provider, but for these to be slaves to a master name server that is maintained behind the firewall of the client organization. The master can perform a transfer of the non-Web site hosts from the master to the slave in a DNS operation called a *zone transfer*.

Another solution is possible that provides a clear distinction between the Web site hosts and the non-Web site hosts—this solution involves creating a subdomain for the Web site hosts. A subdomain would be a third-level domain and would translate a DNS query for the third-level domain into the name server for the subdomain. This name server could be used for just the Web site hosts and could be owned by the Web hosting provider. For this solution to work, a DNS alias would be required that would map a request for `www.client.org` into `www.subdomain.client.org`. The alias (a DNS *CNAME* entry) would be translated and require the third level of name server

lookup. This third level would resolve to the name server of the Web hosting provider. All other DNS queries would resolve at the second level, which would be maintained by a name server controlled by the client organization.

For acceptable performance, DNS entries are cached wherever and whenever possible. This includes the IP addresses of top-level and second-level name servers, and caching can occur both at the end user and at name servers. Cached entries expire after a fixed amount of time, known as the time to live (TTL). The translation entries for second-level name servers are controlled by the domain registrar of the client organization and typically have an expiration time set between twenty-four and forty-eight hours. If a client organization contracts for a new Web hosting provider or changes Web hosting provider, this often involves changing the second-level name servers through the domain registrar. For end users and top-level name servers that have cached the IP address of the second-level name server, such changes will not be visible until after the expiration of the cached entry. This is why a propagation delay is incurred from the time of a name server change to the time when end users can access the Web site through the new DNS entries.

WEB SITE ARCHITECTURES

As we examine the next set of levels in the service component hierarchy (again, see Figure 2), the levels of load balancing, server hardware, operating system, and Web server/database together form the architecture of the Web site. For this reason, we address all four levels in this section on Web site architectures.

At this point, we have moved beyond the services that a colocation provider might offer and are within the realm of the shared server, dedicated server, and managed services provider models. For a shared server, the set of Web site architectures are limited, although fault tolerance and reliability through load balancing may still be achieved. For dedicated server providers and managed services providers, a full range of Web site architectures is possible. It is clear, though, that regardless of the type

of provider, the level of sophistication of the client organization's Web site continues to grow, and Web hosting providers must continue to expand the architectures they support to meet this growing expectation.

A Web site architecture governs the set of hardware servers, their interconnection, and what software components run on what servers. Goals in the design of the Web site architecture include issues of capacity, scalability, reliability, and performance. This section will begin by describing one- and two-tier architectures, followed by the issues of fault tolerance, load balancing, and more advanced architectures.

One and Two-Tier Models

As depicted in Figure 5, the simplest Web architecture consists of a Web server, such as Apache or Microsoft IIS, executing on a physical server and utilizing a host-accessible storage system. This architecture could also incorporate elements such as common gateway interface (CGI)-based scripting in various interpreted programming languages such as Perl, Python, TCL, JavaScript, and server-side technologies such as PHP and Java Servlets. It is beyond the scope of this chapter to investigate the many possibilities entailed. Note also from the figure that the storage could either be directly attached, as in Figure 5a, or it could be separated from the server, as in Figure 5b, such as that enabled by network attached storage or using a proprietary storage area network (SAN, described in the chapter entitled "Storage Area Networks").

When a Web site becomes more dynamic, it often incorporates on-the-fly creation of Web pages using scripting techniques coupled with data contents obtained from a database. This results in the two-tier application model are also shown in Figure 5. As Figure 5c shows, the database software may execute on the same physical server as the Web server, or, as in Figure 5d, it may execute on a second server. When executing on the same server, the Web server software and the database software will be competing for resources. Shared-server providers must be particularly careful because multiple sites share the same Web server and now, in the two-tier model, the same

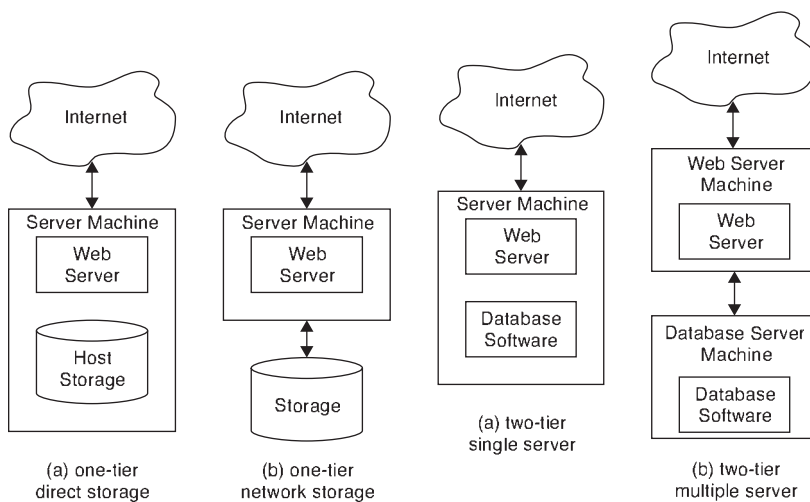

Figure 5: One and two-tier Web architectures

database software as well. In large configurations, the Web and database servers are almost always placed on different physical servers so that these servers may be configured and tuned to meet the performance requirements specific to serving Web pages or to executing a database.

Fault Tolerance

Two approaches may be taken to incorporate greater reliability and fault tolerance in the one-and two-tier architectures. The first is adding redundancy *within* the server. Although a failure of the server hardware could cause a system failure, that possibility can be mitigated by replicating some of the more failure-prone elements of the server. For instance, the Web hosting provider could employ redundant power supplies. Likewise, servers can be configured using Redundant Array of Inexpensive Disks (RAID). This isolates the failure of an individual disk drive and keeps the individual failure from bringing down an entire system or site. Some other intraserver redundancy strategies include replication of the network interface cards (NICs) either in an active/passive failover mode, or in a configuration in which both interfaces are used to transmit traffic, and use of redundant memories and/or ROM for the physical server. A database server might employ a battery backed write cache on the RAID controller. Additionally, server vendors offer options for hot-pluggable components, such as disk drives and other peripheral equipment, so that they can be replaced on the fly while the server continues operation.

The second approach to incorporate greater reliability and fault tolerance is to add redundancy *across* servers. This implies the incorporation of redundant servers for hosting the Web server and/or for hosting the database software. Database redundancy will be discussed further in the forthcoming section entitled "Database Redundancy."

When using redundant Web servers, two styles of fault tolerance are possible. First, one physical server could be the designated *primary*; in the absence of failures, all interaction between an end user and the Web server occurs through the Web server on the primary. When a failure occurs, all new interaction is directed to another machine designated as the *backup*. Upon a failure, the backup must take over the IP address of the primary, or end users must issue subsequent requests using the IP

address of the backup. With a Web server, this simple primary/backup solution works because most end user interactions are *stateless*, with no dependence between one interaction and a subsequent interaction. When a set of end user interactions is grouped together into a session, a failure becomes visible to the end user because the Web server taking over has lost the prior history of the session.

The second style of fault-tolerance actively uses all of the redundant server hardware during the time when no failures have occurred. When done carefully, this redundancy provides benefits of additional scalability and capacity as well. It also requires the use of a new architectural element, the *load balancer*, which serves to distribute load across the set of servers. Although combining this style of active replication with load balancing has the potential to increase fault tolerance, the reality depends on the style of load balancing, which will be discussed next.

Load Balancing

Given a set of interactions between multiple end users and the Web site of a client organization, the function of load balancing for Web site servers is to apportion these interactions among a set of equivalent Web sites. Load balancing involves directing end user traffic to a particular physical server for a Web site. For a single given end user, this interaction may involve multiple request/reply exchanges that are dependent on one another. Thus, for an individual end user, traffic should be directed to the *same* physical server for the duration of the interaction.

Figure 6 shows two examples of load balancing one-tier Web site architectures. Figure 6a depicts a shared server provider scenario, in which the set of Web servers shared on a single machine is replicated on a second server. Figure 6b depicts a dedicated server provider using load balancing between a set of three servers. Note that, in the figure, neither the operating system nor the storage of the Web site content is depicted. The same Web site content must be available to all of the actual Web servers behind the load balancer. For static content, this may be accomplished by mirroring the content between direct host storage. Another alternative is enabled through network storage, whereby the multiple Web site servers could access the same storage.

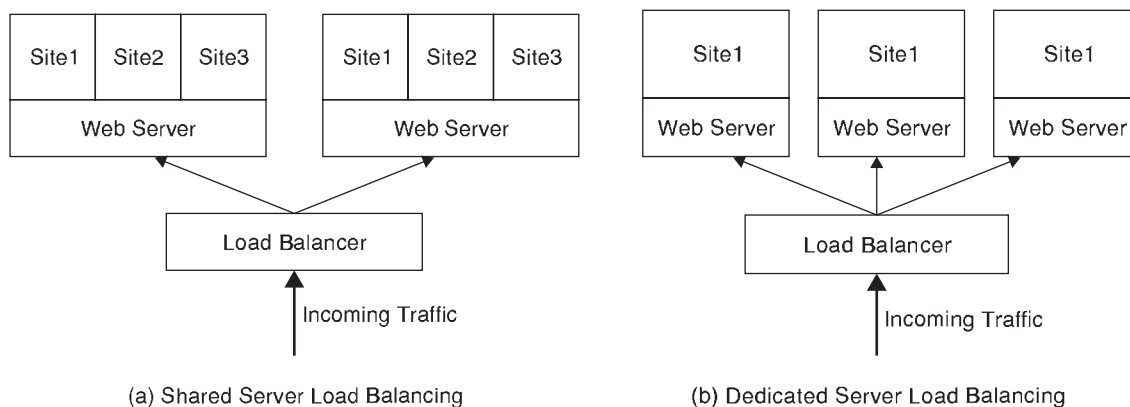

Figure 6: Load-balancing architectures

Two types of load balancing are common: DNS-based load balancing and layer 4/7 switching based load balancing. These load-balancing techniques and more are covered in detail in the chapter entitled “Load Balancing on the Internet.” A brief overview will be presented here.

One of the facilities of DNS is to allow a *set* of IP addresses associated with the resolution of a fully qualified domain name. DNS responds to a request with one of the several translations, and a given DNS name server will rotate through the multiple translations in round-robin fashion. Using this facility, DNS can itself provide load balancing. A given end user performs a DNS operation to resolve the Web site name and receives one IP address, which it uses for the duration of the interaction. Another end user may get a different IP address, and its interaction will be directed to another Web server.

DNS load balancing, however, does not support fault tolerance. In addition to distributing load, we would like our Web architecture to allow that, when a physical server fails, interactions with the failed server cease and subsequent interactions are directed to nonfailed servers. The failure of an individual server does not cause its IP address to be removed from the DNS name server. Thus, end users will continue to be given the IP address of the failed server, and the failure of the server will be apparent.

By way of contrast, layer 4/7 switching load balancing more accurately corresponds to the depiction in Figure 6. An actual hardware device exists, the load balancer, with an associated IP address, that sits between end users and the set of server hardware. The IP address of the load balancer is placed in the DNS name server as the address of the Web site and can be considered the *virtual* address of the Web site. End users initiate interactions with this IP address, and, when connections are received at the load balancer, it translates the virtual IP address to the real IP address of one of the servers, effectively splicing the network connection between the end user and a particular physical server. All subsequent traffic from the same end user during a given connection or session is directed to the same server.

In this load-balancing technique, failures can be handled much more effectively. The load balancer can monitor the health (through heartbeats and/or network activity) and the load on each of the physical servers. When a failure occurs, or when load on a server gets too high, new connection/session requests from end users can be directed to healthy and/or lightly loaded servers.

Layer 4/7 switching load balancing can be accomplished either through hardware or software solutions. Hardware solutions include entries from Cisco Systems (2006), Nortel Networks (2006), Radware Ltd. (2006), and others. A popular software approach creates a load balancer using a Linux server and extending the TCP/IP stack in the kernel. This work has been gathered together under the name Linux Virtual Server (LVS; 2006), and includes layer 4 switch load balancing through the kernel module IP virtual server (IPVS) and layer 7 application level load balancing through the kernel TCP virtual server (KTCPVS).

Modern load balancers are capable of significant intelligence in performing their function. They can route requests for specific URLs to a single or a small set of servers. They can also make decisions based on protocol,

so that HTTPS requests may be directed differently than HTTP requests.

The distinction between layer 4 and layer 7 switches involves what protocol-level information is used to determine a correspondence between an end user and a physical server. At layer 4, the correspondence is determined by a TCP connection, and all packets within the same connection are directed between the same end user/server pair. At layer 4, different TCP connections from the same end user can be directed to different servers. At layer 7, higher-level session information is used to determine the correspondence so that multiple TCP connections that are within a higher-level session are still directed between the same end user/server pair.

Advanced Architectures

As Web sites become more complex, the set of architectural variants can become quite numerous. In this subsection, we will highlight a few of the directions that Web site architectures can progress, and note some of the implications on Web hosting.

Two-tier Web site architectures employ the combination of the database and scripting techniques to define the operation of database-driven Web applications. As the load to the Web site increases, this architecture can suffer in performance. Each interaction between end user and Web site is separate, and, when scripting and making requests of the database are involved, each interaction results in a separate process. This implies many short-lived processes along with a lack of ability to maintain state over a set of interactions. An alternative is to extend the architecture with another element known as the *application server*, as depicted in Figure 7. The application server can maintain state and a single logical connection with the database and respond to a set of individual interactions from the Web server. In the three-tier model, the application server can also be replicated for additional fault tolerance. An example redundant three-tier architecture is also depicted in Figure 7.

Geographic Distribution

Geographic distribution refers to the redundancy of Web servers at multiple geographically distributed locations. This level of redundancy offers protection against natural disasters or Internet routing problems that can potentially make an entire single data center unavailable. It does so, however, at additional complexity and cost.

Database Redundancy

Databases are more complex to replicate than are Web servers. Consistency of data through atomicity of updates is a requirements of databases, and the addition of redundant copies of the database must be handled with care. All of the examples shown thus far have only included a single copy of the database. The subject of database redundancy is beyond the scope of this chapter.

Caching and Content Delivery Networks

Performance is an issue of great concern to client organizations. Some of the Web site architectures we have examined, particularly those that employ load balancing,

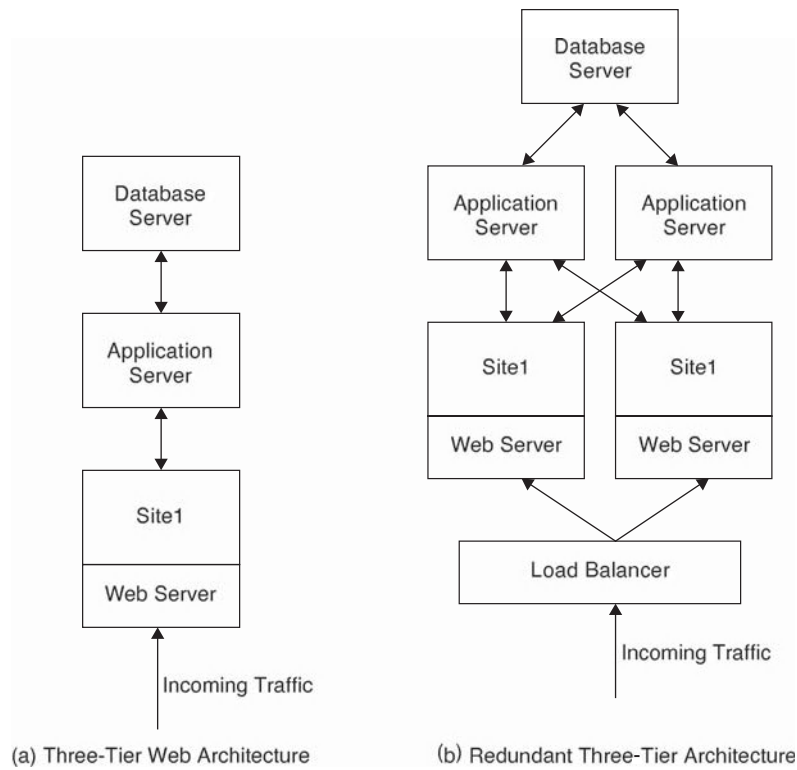

Figure 7: Three-tier architectures

can improve the scalability and the end user performance of the Web site.

Another common technique used to improve performance is that of caching of Web site contents. Caching distributes Web site contents, such as Web pages and images, and places them at locations closer to the end user. End users make requests for Web pages and images, when these requests are received by a cache, and if the cache has stored the requested elements, the request can be serviced immediately, and does not continue to the Web server.

Caching of Web site content occurs on many levels, from within the browser and file system of the end user, to corporate and organizational level proxies. Most caching has little impact on Web hosting because it occurs at locations closer to the end user. The effect on Web hosting is indirect, because successful caching reduces the volume of requests that are directed to the web site at the web hosting provider data center. This results in reduced revenue for the Web host vendor because request bandwidth and storage are the two primary metrics used by Web host providers to determine the price associated with hosting a Web site.

Another form of caching that also has the effect of reducing traffic volume to the hosted Web site is known as *content distribution networks* (CDNs). In this case, end users are directed through DNS lookups to one of a distributed set of sites caching content for a given Web site. These cache locations are placed at *edge devices*, whose network location may be closer to end users. The end user then interacts with the CDN cache instead of interacting with the original Web site.

The topics of caching and content distribution networks are described in much greater detail in the chapter entitled “Load Balancing on the Internet.”

CONCLUSION

This chapter has described the topic of Web hosting, an arrangement by which an outsourcing organization, specializing in Web site infrastructure and management, provides this Web site hosting and management for a client organization. This is typically a many-to-one relationship, with potentially many client organizations being served by a single Web hosting provider.

The chapter has examined the two dimensions in the organization of such a relationship. The first dimension includes the provider models by which multiple clients may be supported, along with the services that may be provided by the outsourcing organization. Central to the provider model design and the support of a multiplicity of clients, the network issues are a primary focus of the chapter. The second dimension includes the Web site architectures that may be required of different client organizations and how the Web hosting provider may support those architectures. It is the merging of these two dimensions into a coherent whole that really defines a particular Web hosting solution.

GLOSSARY

Colocation Model: A Web hosting provider model in which the services provided are limited to the physical facilities and Internet access.

Dedicated Server Model: A Web hosting provider model in which a client organization's Web site is placed on one or more dedicated physical servers of the provider.

Fault Tolerance: The ability of a system to provide availability of operation in the presence of hardware or software failures of individual components.

Internet Data Center (IDC): The physical infrastructure for Web site servers including physical plant, power, air conditioning, and Internet connectivity.

Load Balancing: The partitioning and apportioning (directing) of a set of network interactions between end users and a set of physical servers.

Managed Service Provider: A Web hosting provider model in which the services include customized design of the Web site architecture to meet advanced requirements of the client organization.

Outsourcing: The contracting of services with an external provider instead of providing the services within an organization.

Profile Hosting: A form of shared server hosting in which a specialized form of user Web site, the *member profile*, is hosted for large numbers of users.

Satellite Data Center: An additional IDC serving as an adjunct to a primary IDC.

Service Component Hierarchy: The layered architecture of services offered by Web hosting providers.

Shared Server Model: A Web hosting provider model in which multiple Web sites are placed on the same physical server owned by the provider.

Virtual Private Servers: A variant of the shared server provider model in which each client organization is allocated a virtual machine to provide greater isolation between Web sites.

Web Hosting: An arrangement by which a company that specializes in the ongoing management of the technology and resources to run a Web site provides such a service for another company, organization, or individual.

INTRODUCTION TO END-SYSTEM QOS

The Internet has become a mainstream medium for distributed applications with various demands for reliability, availability, security, privacy, timeliness, and network bandwidth. These properties are often called *quality of service* dimensions. The new demands call for both network and end-system architectures for performance guarantees to satisfy quality of service. Deployment of QoS architectures at the application layer has been much more successful than at the network layer. The lack of support for network-layer architectures such as int-serv, RSVP, and diff-serv is attributed in part to the lack of a good pricing model for network QoS, the lack of appropriate enforcement, and the lack of an end-to-end solution that spans multiple administrative domains and is upheld by all Internet service providers (ISPs) on the path of a client's packet. In the absence of an agreed-upon end-to-end solution, incremental deployment of QoS mechanisms by a subset of ISPs is not enough to guarantee QoS and does not encourage client buy-in. In contrast, end-system solutions can be implemented and priced entirely within a single administrative domain, which explains their recent success. In this chapter, we first review the main components of the Internet service architecture and describe the protocols that govern their interaction. We then discuss how this architecture and these protocols are affected by QoS considerations, and explore the different performance considerations that emerge specifically in QoS-aware end-systems.

Generally, research on end-system QoS focused on three major directions. The first and most widely explored direction was developed in the context of multimedia applications (Jin and Nahrstedt 2004). With the proliferation of audio and video streaming, much work focused on end-system approaches to improve multimedia quality. This work can be partitioned into server-side approaches and client-side approaches. On the server side, operating system support was developed to provide QoS-aware services

to multimedia flows. This includes real-time extensions to common operating systems, resource management extensions to expedite handling more urgent flows, transcoding and distillation work that transforms multimedia quality depending on channel conditions and client-side limitations, and mechanisms for differentiated access to resources such as virtual memory and I/O. On the client side, multimedia research focused on operating system support for real-time playback of received flows, including support for resource reservation and application-aware prioritization.

A second important direction in QoS research concerns itself with peer-to-peer systems and applications. One thread under this category is to use P2P networks for application-level routing in a way that achieves better perceived network performance for premium flows (Rakotoarivelo et al. 2005). QoS-aware overlay topologies received much attention (Subramanian et al. 2004). Another important category addresses download speeds in P2P file distribution networks. Mechanisms are developed to ensure QoS in the presence of topological changes and neighbor turnover (Bindal and Cao 2006). Yet another important direction considers wireless networks (Zhu et al. 2004), where additional challenges arise because of lack of structure and frequent changes in the underlying physical topology and resource availability. Recently, some approaches focused on achieving QoS by jointly considering coding techniques and P2P data distribution. For example, erasure coding was proposed in P2P networks to improve transfer throughput (Dairaine et al. 2005).

Finally, much QoS research addressed the performance of the Web infrastructure. This direction focused on extensions to Web servers and Web proxies to provide acceptable content access latency to clients. The current chapter focuses on this last direction. We do not focus on multimedia applications and networks because these are covered elsewhere in the book (e.g., see "Multimedia Streaming," "Internet Domain Name System," and "Mobile Commerce").

Many of these approaches rely on network or operating system extensions that are covered elsewhere (see “Telephone Number Mapping (ENUM)” for network QoS and “Packet Switching,” and “Circuit Switching” for operating system coverage). We also do not cover peer-to-peer issues because these are discussed in much detail in Part 1 of Volume III (for example, see “Network Capacity Planning” and “Network Traffic Modeling”). We concentrate in this chapter on wired networks. Wireless network issues are described at length in Part 3 of Volume II (wireless and cellular).

In addressing QoS assurances in the rest of this chapter, we focus on time-related metrics such as latency. Time-related metrics are key attributes of system performance, but are not the only ones. QoS research broadly covers other attributes as well such as reliability and security. These are covered elsewhere in this book. For security issues, please see “Web Hosting,” “Computer Conferencing: Protocols and Applications,” and “Telecommuting and Telework.” For reliability, see “Firewalls.” In general, research on time-related metrics can be partitioned into hard real-time and soft real-time assurances. The former is typical to military systems, avionics, and other applications where missing timing requirements can have catastrophic consequences. Because current Internet applications do not fall in this category, this chapter focuses on soft real-time assurances, where correct temporal behavior is desirable but some flexibility exists.

End System Architecture and QoS Implications

The questions this chapter addresses are why end-system QoS emerged as a new challenge area, and what makes this challenge important. Today, many critical business, personal, and entertainment transactions use the Internet. Improving the performance of such transactions, therefore, has dramatic global effects. Efforts to improve performance come in two flavors. First, infrastructure improvements are pursued, such as realizing higher bandwidth, faster servers, and better last-mile technologies. This is largely a cost and capacity provisioning problem that motivates development of lower cost facilities and higher capacity switches and routers. Concurrently, a substantial amount of research is done to make Internet performance more *predictable*. Performance is said to be predictable when its quality can be *guaranteed* in advance. Many societal and commercial forces contribute to this need. In particular, the commercialization of the Internet and the pricing of many Internet services play a significant role in elevating the idea of performance guarantees from a value-added option to a primary concern driven by contractual obligations.

In traditional commercial products, commercial users have grown to take quality guarantees for granted. Vendors have contractual obligations to accept returns of defective products or products that do not perform as advertised. Similarly, paying consumers of Internet-based services expect a performance guarantee or a money-back statement. Much as with other services, it will be important that clients and service providers be able to negotiate mutually acceptable quality levels in the service contract

for a corresponding price. QoS-violations can therefore result in monetary losses to online business.

This relation between performance guarantees and revenue is manifested today in several domains. For example, ISPs often sign mutual service level agreements (SLAs), which among other things describe the performance that the traffic of one ISP should receive in the network of the other and the corresponding fee. Closer to the end user, online trading services sometimes tie their commission fees to performance in executing the trades. The fee is waived for trades that are delayed by more than a specified amount of time. In view of this emphasis on performance as a contractual obligation, a significant amount of research has been spent on architectures that enforce quality of service guarantees on end systems. These include mechanisms and policies for QoS provisioning, QoS negotiation, and utility optimization as well as means for protection against QoS violations.

The Need for QoS Support

Most popular QoS attributes of importance from an end-system perspective revolve around some notion of time. For example, guarantees may be needed on delay, or on the number of requests served per unit of time. We call such metrics, *temporal*. A significant body of literature has addressed the issue of guaranteeing temporal QoS attributes in the absence of adequate prior knowledge of operating service conditions such as load and resource capacity. Until recently, the current state of the art in providing acceptable temporal performance to the users has been over-design. Throwing money and hardware at a performance problem eventually ensures that there are enough resources to service incoming requests sufficiently fast. This approach, however, is inadequate for several reasons. First, it is rather expensive, because more resources are expended than is strictly necessary. Second, it provides the same service to all clients. In many cases, however, a service provider might want to use performance differentiation as a tool to entice clients to subscribe to a “better” (and more expensive) service. Third, the server provides only a best-effort service in that there are no bounds on worst-case performance. It is sometimes advantageous to be able to quantitatively state a performance guarantee for which users can be commensurately charged.

In this chapter, we describe performance guarantee mechanisms for server end systems with an emphasis on enforcement considerations that prevent QoS violations. As a running application example, consider a server farm that hosts multiple services (e.g., data retrieval services in a data center) on behalf of different content providers. Software and data service hosting is a large business in which major investments are made by companies such as Intel, IBM, and Hewlett Packard. We discuss the type of performance guarantees required, the parties to whom the guarantees are made, and the mechanisms used to enforce these guarantees in the face of denial-of-QoS attacks. The server farm example provides a context for describing the general classes of server performance challenges and helps illustrate solutions needed when resources are shared among multiple parties with different QoS requirements.

A server farm end system interacts with at least three different parties: (i) end users who access the hosted content; (ii) content providers who own the content, services, or software exported for hosting; and (iii) network providers who provide Internet connectivity to the hosting farm. End users are typically interested in a fast response time; content providers care more about throughput, which translates into total capacity dedicated to their hosted sites; and network providers care primarily about network bandwidth consumed by the hosting installation.

In general, the mechanisms to provide these guarantees lie either on servers (i.e., on the end system) or inside the network. Many QoS mechanisms inside network such like IntServ and DiffServ have been proposed in the past 15 years. These technologies usually require network users to make “reservations” so that different types of network service (traffic) will receive different qualities in terms of delay, packet drop ratio, and so forth. While these QoS mechanisms on the network layer are vital for successful end-to-end QoS guarantees, their widespread deployment is yet to be realized. On the other hand, QoS guarantee mechanisms on the end system have been widely adopted by various operating system kernels and commercial application server products. In the following sections, we describe several approaches for end-system QoS guarantees in more detail with emphasis on Web applications.

Example: The World Wide Web

Several middleware components such as SOAP may be used to build and interface myriads of distributed services for client applications. Such services may deal with content distribution, information retrieval, content processing, or data storage. QoS in component architectures has, in fact, become an interesting research area. Different applications would typically use their own special-purpose service components, accessed by application clients. These components will be hosted by third-party hosting providers. Popular protocols, such as HTTP/1.1 (Mogul 1995) govern data exchange with clients.

In addition, because much of the Internet architecture is geared for content retrieval, an important general class of services is that of content distribution and caching. To improve service access delays and reduce backbone traffic, caching and content distribution services have gradually emerged. These services attempt to redistribute content around the network backbone so that it is closer to the clients who access it. The difference between caching and content distribution lies in a data-pull versus a data-push model. Whereas caches store content locally in response to user requests, content distribution proxies proactively get copies of the content in advance.

In this chapter, we take the architecture of the World Wide Web as a running example, and use this architecture to describe QoS concepts. In the Web architecture, there are generally three types of caches, namely proxy caches, client caches, and server caches. Proxy caches, shown in Figure 1, are typically installed by the ISPs at the interface to the network backbone. They intercept service requests originating from the ISP's clients and save copies of the requested pages when replies are received from the contacted servers. This process is called page

Figure 1: Web proxy caching

caching. A request to a page that is already cached can be served directly from the proxy, thereby improving client-side latency, reducing server load, and minimizing backbone traffic for which the ISP is responsible to the backbone provider. An important question is what to do when the cache becomes full. To optimize its impact, a full cache retains only the most recently requested results, replacing those that have not been used the longest. This is known as the least-recently-used replacement policy. Several variations and generalizations of this policy have been proposed, e.g., to account for page size, cost of a page miss, and the importance of the client.

To improve performance further, client application software (e.g., browsers) locally caches the most recently requested pages. Finally, some server installations use server-side caches (also known as reverse proxies) to reduce the load on the server. The caching infrastructure significantly affects the user-perceived service performance. Arlitt, Friedrich, and Jin (1999) compare the effects of different replacement policies on cache performance. Recent research efforts address developing caches that provide some form of performance differentiation or QoS guarantees. A proxy cache, for example, can offer preferential treatment to content requested by a certain subset of clients or content belonging to a certain subset of providers. This mechanism will be described in later sections.

Content Distribution Networks (CDN) are another technology that enables scalable content delivery from content providers to clients. Compared to caches, CDNs have the advantage that content can be pre-populated to the proxies based on the business relationships between CDN providers and content providers. Next, we describe the types of performance guarantees needed in the services described above.

PERFORMANCE ISOLATION

The most basic guarantee needed among multiple traffic classes is that of performance isolation. Informally, the guarantee states that the performance seen by any particular class of clients should be independent of the load imposed by any other class. For example, consider

an end system that hosts two services, A and B. Unless proper action is taken, an overload on B may slow down the entire server, preventing the clients of A from accessing the server as well. Performance isolation mechanisms resolve the problem by imposing limits that prevent (clients of) any one hosted service such as B from monopolizing the server. Hence, performance isolation localizes the effects of denial-of-QoS attacks. It acts as a fault-containment mechanism in fault-tolerant architectures. There are several different ways performance isolation may be implemented. They typically rely on some form of resource allocation and admission control. In the following subsections, we discuss some of the most important mechanisms for performance isolation in the operating system, middleware, and application layer.

Operating Systems Solutions

The core mechanism for performance isolation is resource reservation. Each service must be allocated its own resource quota on the end system. Requests for that service are allowed to consume only those computing resources that are within its quota. Excess load on one service should not be allowed to divert resources dedicated to others. Traditionally, resource allocation and management is the responsibility of operating systems. Hence, the most fundamental solutions to performance isolation are operating system solutions.

Generally speaking, in a shared computing system, such as a server farm shared by multiple cohosted services, common resource sharing can be categorized into two different types; sharing in time and sharing in space. Predominantly space-shared resources include, for example, memory and disk space. Different processes may own different subsets of the resource concurrently and be denied access to resources owned by others. Space-sharing implies that the resource can be partitioned. Some resources, however, are indivisible. The prime example is the CPU. Indivisible resources can only be allocated in their entirety to one process at a time. However, they can be given to different processes at different time, and therefore time-shared. Clients are queued up on the time-shared resource. The queuing order and duration of resource access allowed by each client decide how the resource is shared.

Traditional operating systems such as UNIX implement a time-sharing scheduling policy, which allocates the processor one quantum at a time in a round-robin fashion among the waiting processes. This policy is inadequate for performance isolation in that it allows one class to affect performance of others. Consider our server farm example, where it is desired to isolate requests for different services cohosted on the same platform. The CPU capacity available to one service under the UNIX time-sharing scheduling policy is roughly proportional to the number of processes serving the corresponding service clients at a given time. This number is in turn proportional to the client request rate. A very popular service will have a large request rate which generates a large number of processes to serve these requests. It can monopolize the CPU.

To ensure performance isolation, many researchers have addressed the problem of reservation of time-shared resources. The first effort on this subject came from the

Real-Time Mach project at Carnegie Mellon University and is called *processor capacity reserves*. The idea of processor capacity reserves is to implement separate accounting entities (the reserves), which keep track of the processing budgets allocated to abstract CPU activities. For example, a programmer can associate a budget with each separate service on the hosting server. The budget specifies the percentage of time that the CPU is allowed to spend on the corresponding site (e.g., 4ms every 30ms). The budget is replenished periodically. To enforce performance isolation, when a server end-system receives a request, the request is classified and the corresponding budget is charged for the time it takes to serve the request. If the reserve is exhausted before the end of the period, the budget is said to have expired. When a budget expires, processes charged to that budget are blocked until the next replenishment period. Hence, these processes cannot jointly exceed the CPU allocation specified for the service they implement.

One limitation of the aforementioned technique is the way accounting is done in the operating system. The party that the CPU is working for at any given time is identified in the operating system as either the kernel or a particular user process. Hence, only total kernel execution time and the total execution time of any single process can be measured. In particular, kernel execution time is not properly broken into independent activities. For example, the kernel-processing time of incoming requests is not properly attributed to the site for which the requests are destined and is thus not charged properly to the correct reserve. The problem is exacerbated by the inability to differentiate connections until they have been processed by the TCP/IP stack. To address the aforementioned accounting problem, resource containers (Banga, Druschel, and Mogul 1999) have been proposed as a new operating system abstraction for resource reservation and performance isolation in monolithic kernels running server end systems. The authors of this approach make the observation that the accounting problem arises from the fact that in traditional operating systems the resource principal (i.e., the system entity capable of owning resources) is generally associated with a protection domain (such as a process). In server end-systems, this association is not appropriate. The logical resource principal could be a user or a content provider. Depending on the server architecture, multiple processes can serve the same principal, or a single process can serve multiple principals. The resource principals should be charged for processing that occurs both on the kernel level and in user space. Banga et al. (1999) propose the abstraction of resource containers to resolve the dichotomy. In this approach, packet filters are placed at the lowest level of the end-system protocol stack. These filters demultiplex incoming traffic into distinct categories (e.g., by IP address). All kernel and user-level processing of traffic in each category is charged to the corresponding resource container. As before, when the container is exhausted, the operating system stops processing the corresponding traffic type until the container is replenished. The approach has been shown to provide excellent isolation. It is also very efficient in isolating denial-of-QoS attacks. For example, if the identity of the attackers is known, all traffic from

them can be isolated and associated with a separate resource container of zero capacity. This traffic will thus be dropped, causing no negative effects on the rest of the system.

The need for early demultiplexing presents several challenges of its own. Such demultiplexing is typically performed based on fields in the TCP or IP headers. Unfortunately, in many cases, client classification is a little more complex (Menasce et al. 2000). Designing general-purpose mechanisms to express such classification constraints at the operating system level is a challenging task, unless one is willing to sacrifice the application-independent nature of general-purpose operating systems.

Another complication is that packets arriving at the bottom of the protocol stack (e.g., IP fragments) may not always have an application-layer header, which contains the information necessary for classification. These headers would be reconstructed higher in the communication protocol stack, which makes early classification more challenging. Construction of efficient packet filters for early classification based on application-specific information is therefore an important research challenge.

Middleware Approaches

When client classes are defined in an application-specific manner, a different solution to performance isolation is to develop middleware that augments generic operating system support with application-specific middleware policies. The operating system approach, described in the previous section, is perhaps the most efficient approach for fine-grained performance isolation. However, it suffers from the lack of generality and the lack of portability. The former refers to the difficulty of incorporating application-specific classification policies into the kernel. The latter (i.e., portability) stems from the fact that support for time-multiplexed resource reservation described above is still far from being a standard operating system feature. Thus, performance isolation solutions that do not *require* this support in the operating system are often preferred. These considerations lead to middleware solutions.

Middleware refers to any software layer that runs below the application and above the operating system. Generally, there are two types of middleware; that which is transparent to the application and that which requires application modification to adhere to a new interface. The former is more general in that it does not require access to application source code. Hence, a hosting service, for example, can develop in-house middleware components even when the source code for the Web server and the operating system is not available. Similarly, a middleware vendor can develop its software independently to interoperate with multiple application and operating system products without the need to modify their code.

An important challenge in designing transparent middleware support is to architect the (transparent) interaction with the server software. Such interaction is usually implemented by instrumenting standard dynamic shared libraries used by the server. Dynamic shared libraries are those loaded by the server at run time, as opposed to being precompiled together with server code. This feature is made possible due to late binding, supported by most

operating systems today. In late binding, references to called library functions are not resolved until the call is made at run time and the corresponding library is dynamically loaded into the server's memory. It is therefore possible to make changes to the shared library without having to recompile or relink the server software. Once the server makes the standard library call, the new (modified) library gets invoked. In the case of middleware for performance isolation, the modified shared library may implement accounting functions that approximate resource containers.

One of the most obvious libraries to instrument is the socket library. Hewlett Packard Labs researchers (Bhatti and Friedrich 1999) were the first to suggest architectures where the socket library is replaced with a QoS-sensitive version, which implements performance isolation. In the context of regular socket calls, the QoS-sensitive library dequeues service requests from the server's well-known port and classifies them into per-class queues. The `accept()` or `read()` socket calls are modified so that no connections are accepted from a given per-class queue unless the budget of the corresponding class (maintained by the modified library) is nonzero. The scheme, shown in Figure 2, implements approximate performance isolation. It has been successfully integrated into a server platform sold by Hewlett Packard, called WebQoS.

A frequently encountered problem with middleware approaches to performance isolation is their larger overhead. All requests (regardless of their importance and regardless of server load) have to be processed by the operating system before reaching the middleware layer where they are classified and handled in accordance with their class. Hence, in cases of severe end-system overload, the number of incoming requests may become large enough that their operating system processing overhead alone is sufficient to saturate server resources. The server, therefore, performs no useful work since application-layer software never gets to run. This is called live-lock. It is a price paid for the convenience of implementation and generality of the mechanisms.

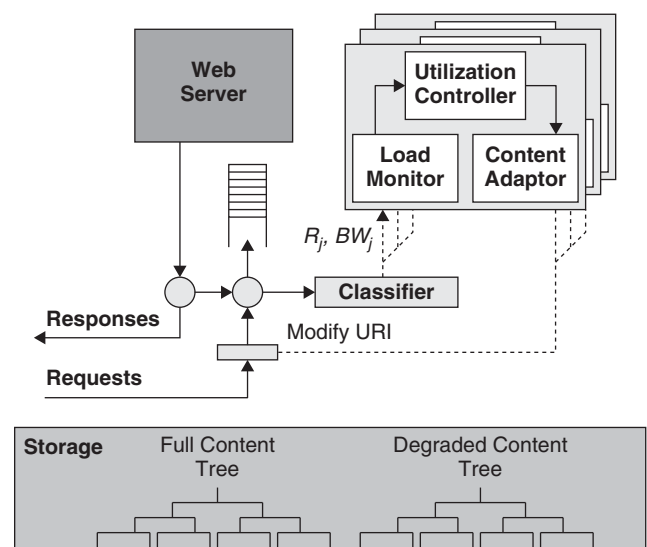

Figure 2: A middleware architecture for Web QoS

An interesting new direction in middleware-based QoS is to add QoS-awareness to component-based architectures such as CORBA, DCOM, and .NET. If the individual components are QoS-sensitive, their composition may satisfy certain QoS guarantees. This class of middleware is sometimes referred to as DRE systems. Models for composition (Xiao and Boutaba 2005) and adaptation (Schantz et al. 2006) of performance properties are therefore needed. These models are often very hard to obtain. On the surface, the composition problem is simple. For example, end-to-end throughput of multiple component is the throughput of the bottleneck. End-to-end delay is the sum of delays of the individual components. The problem arises due to unexpected interactions among the components. For example, adding components on a given machine may eventually run into physical memory limitations, leading to thrashing which increases delay disproportionately. Synchronization and use of semaphores can also cause unpredictable effects on delay when components are put together. In large systems, it is very difficult to model and predict how components compose, making distributed component-based architecture an important QoS topic.

Application-Layer Mechanisms

Current state-of-the-art application servers, such as the Apache Web Server (the most widespread Web server today), maintain a single process pool for all incoming requests. The single-pool architecture significantly complicates QoS provisioning because all requests are treated alike in the server. Hence, a popular class can send a large number of requests to the server until the entire process pool is consumed, thereby denying QoS guarantees to other client classes. In a multi-class server, attainment of performance isolation can be significantly simplified if the server is designed with QoS guarantees in mind. The single main feature that provides the most impact is to maintain a separate pool of processes for each traffic class. Once the server identifies an incoming request as belonging to a particular class, it is queued up for the corresponding process pool. Hence, it is possible for clients to continue to use their quota of server processes regardless of load on other classes. Several examples of this architecture have been proposed in the literature. QoS provisioning amounts to controlling the resource allocation of each separate pool.

SERVICE DIFFERENTIATION

An important second category of QoS guarantees is service differentiation. The goal of performance isolation, discussed above, is to logically *partition* the resource so that each class of clients would get its own independent portion. Competition among classes is *eliminated* by giving each exclusive ownership over a subset of resources. Faults and overload are localized to individual resource partitions and hence are conveniently contained. In contrast, service differentiation policies do not attempt to partition the resource. The resource is *shared*. When the resource is in demand by multiple classes, the differentiation policy *resolves* the competition in a way that favors some class over others. Service differentiation policies are classified depending on what it means to “favor” a particular class.

Informally, to borrow travel metaphors, performance isolation is analogous to a timeshare in which your contract guarantees, say, three weeks per year. You can always redeem up to three weeks regardless of who else has a contract for the premises. Indeed, the resource is “shared” but each principal has its own guaranteed quota. In contrast, service differentiation is analogous to airline “waitlists.” When room is available, it is assigned in some competitive manner. Your chances of getting the resource (e.g., getting on the plane) depend on your priority (or the differentiation policy in general) and the available resource supply.

Some authentication mechanisms are needed to make sure that selfish or malicious clients cannot impersonate an important client class and send unauthorized requests that degrade service to authorized clients. Authentication refers to the act of verifying client identity to prevent identity theft. A server should not treat a client preferentially until the server has determined that this client is entitled to the preferential service. In the following sections, we describe the most common examples of service differentiation and their enforcement mechanisms.

Prioritization

The simplest method to provide differentiation is prioritization. Consider a situation where a service is accessed by two classes of clients: paying customers and nonmembers. The server offers two types of service; premium and basic. Assume that a dedicated authentication server exists that ensures that only authorized (i.e., paying) clients can get premium service. In contemporary service architecture, paying customers are usually allowed access to protected service functions that are inaccessible to nonpaying users. In other words, differentiation among class is typically in terms of available service functionality. This type of differentiation, however, is often inadequate. It is equally important to differentiate in terms of service performance as well. For example, if the end system is overloaded, all functionality will degrade in no relation to the client class unless provisions are made to degrade performance of lower-class (e.g., nonpaying) clients before that of higher-class (e.g., paying) clients. Performance isolation can be applied between paying and nonpaying users, but it suffers the problem of having to decide on the relative sizes of the respective resource partitions, which typically depend on the current load. One approach to circumventing this problem is to serve clients in absolute priority order. In this scheme all client requests are queued up in a single priority queue for server access. Under overload, the queue overflows. Clients at the tail of the queue are dropped. These clients, by construction of the queuing policy, are the lower-priority ones. The mechanism ensures that nonpaying clients cannot degrade the performance of paying clients.

The problem with prioritization alone is that it fails to provide meaningful performance guarantees to the low-priority clients. The top priority class receives the best service, but very little can be predicted about the performance received by other classes. Prioritization, however, becomes an extremely useful analyzable tool once combined with admission control techniques discussed below.

Absolute Delay Guarantees

Prioritization, in conjunction with admission control, allows providing customizable absolute delay guarantees to an arbitrary number of client classes. Consider a case where there are N classes of paying clients. To recover a fee, the server end-system is contractually obligated to serve each class within a maximum time delay specified in the corresponding QoS contract signed with that class. For example, in an online trading server, first-class clients may be guaranteed a maximum response time of 2 s, whereas economy clients are guaranteed a maximum response time of 10 s. Failure to execute the trade within the guaranteed response time results in a commission waiver. Alternatively, in a content hosting service, the content provider of each hosted site might have a QoS contract with the host that specifies a target service time and a fee paid to the host per request served within the agreed-upon delay. Hence, an overloaded hosting server, which consistently fails to meet the delay constraints, will recover no revenue from the content providers.

Because, in these examples, a host does not derive revenue from requests that miss their deadlines, admission control may be used against clients who are unlikely to meet their timing constraints. The rationale for such admission control is that scarce server capacity should not be wasted on clients who are unable to make revenue. Although theoretically, admission control refers to a choice between acceptance and rejection, it is more realistic to choose between acceptance and *background service*. In other words, for the purposes of the following discussion, a rejected client is put in a separate lowest-priority queue to be served if resources permit.

Admission control has received much attention in QoS literature. Admission control algorithms may be classified into optimistic and pessimistic. The former type may admit clients optimistically even when they may miss their deadlines. The latter may reject them unnecessarily. Note that absence of admission control can be thought of as the extreme of optimistic admission control tests. Recent results (Abdelzaher and Lu 2001) have shown that in a server with randomly arriving requests, it is possible to use a constant-time admission control test to distinguish clients who will meet their deadlines from those who may not. The test is based on a running counter, which maintains a utilization-like metric. The counter is updated by a constant-time operation upon request arrivals and departures. If a request arrives while the counter is below a certain high-water mark, it is guaranteed to meet its deadline. Otherwise, the deadline may be missed and the request is served at the lowest priority level. Recent evaluation results of this admission control algorithm show that it rarely errs in the sense of unnecessarily rejecting requests. The test is shown to improve revenue at overload, not only by eliminating resource consumption wasted on requests that miss their deadlines but also by favoring smaller requests (all other factors being equal) and hence improving server throughput. The derivation of the high-water mark representing the client admission threshold assumes that clients are served in a priority order such that more urgent requests are served first. A generalization of this test has later been proposed for FIFO scheduling.

When priority-driven scheduling is used to meet deadlines, priority should be set proportional to urgency. There are two ways urgency can be defined. In the first, clients with shorter per-class response times are considered more urgent. The resulting priority assignment is called deadline-monotonic (or rate-monotonic if requests are strictly periodic). In the second, urgency is defined by absolute deadline. The resulting priority assignment is called earliest-deadline-first (EDF). For example, consider a request arriving at time 0 with a maximum response time constraint of 10 s. At time $t = 9$, a second request arrives of a different class with a maximum response time constraints of 2 s. According to the deadline-monotonic priority assignment, the second request should receive higher priority because its maximum response time constraint, 2, is tighter than 10. According to EDF the first request should receive higher priority because its absolute deadline is $0 + 10 = 10$, which is before the absolute deadline of the second request, $9 + 2 = 11$.

EDF has been proven to be the optimal priority-driven scheduling policy. Deadline-monotonic scheduling is optimal among time-independent scheduling policies (i.e., those where priorities are assigned independent of absolute request arrival times). Optimality, here, is defined in terms of the ability to meet a larger number of deadlines. EDF can meet deadlines when deadline-monotonic scheduling fails because it takes arrival times into account. For instance, in the above example, if the first request has an execution time of 9.5 s, and the second request has an execution time of 1.5 s, both requests meet their deadlines under EDF, but not under deadline-monotonic scheduling. A problem with EDF is that it is less commonly implemented on standard operating systems, with the exception of embedded real-time operating systems where application timing is of prime importance. Deadline-monotonic scheduling is therefore a good compromise.

Statistical Delay Guarantees

An entirely different line of reasoning is to provide statistical guarantees on delays and deadline misses. Statistical guarantees require queuing analysis of the end system. This analysis makes two types of assumptions. First, it must make assumptions regarding the queuing structure of the server. Second, it must make assumptions regarding the request arrival process. In the following, we outline the most important challenges underlying the statistical approach to QoS guarantees on end systems.

Consider the first challenge, namely, deriving the queuing structure of the end system. This queuing structure depends on the service protocol used. Consider a typical multithreaded (or multiprocess) Web server. Packets arrive from the network, causing hardware and software interrupts that, respectively, read the packets from network interface cards and deposit them into a kernel-level input queue called the *IP queue*. In between interrupts, packets in the IP queue are processed by the kernel and queued for the particular application ports for which they are destined. These ports are often called sockets. Each socket is associated with an input queue, called the *listen queue*, where incoming connection requests are queued. Independently schedulable entities in the server end system, called *worker threads*, are blocked for data to be deposited

at the listen queue. These threads are unblocked by request arrivals to execute the arriving requests. Each thread implements a loop that processes each incoming request and generates a response. Worker threads that have been unblocked by request arrival become runnable.

Multiple runnable threads may exist at a given time. The order in which such threads get the CPU to execute a request is determined by the CPU scheduling policy. This policy maintains a priority queue called the *ready queue*. The thread at the top of this queue executes for a particular time quantum or until it is blocked. Request processing by a worker thread typically entails access to one or more auxiliary server resources, the most notable being disk I/O. Access to auxiliary resources blocks the calling thread, at which time it is queued for I/O until the awaited resource becomes available. Each resource usually has a queue, which determines the order in which accesses are served. We call it the *I/O queue*. The resource is made available to the thread at the top of the queue, at which time the corresponding thread becomes runnable again and re-enters the CPU ready queue. When request processing is done, the worker thread sends a response back to the client. Sending the response entails queuing data into the *outgoing packet queue* for transmission on the network.

The above discussion identifies five different queues involved in the server's queuing structure: namely, the IP queue, the listen queue, the ready queue, the I/O queue (assuming a single I/O resource, such as, disk), and the outgoing packet queue. The interconnection of these queues creates a queuing network with loops and other dependencies. For example, threads that repeatedly read and process disk data essentially loop between the ready queue and the I/O queue. Moreover, when the number of threads is fixed, dequeuing from the listen queue is synchronized with progress in the ready queue in that new requests are dequeued from the former only when some runnable thread has finished serving a request or has blocked. These factors make accurate analysis of the server's queuing structure difficult. Instead, many approximations are possible. For example, it is possible to consider only the queue for the bottleneck resource. The general idea is that a service request is likely to spend most of its time waiting in the bottleneck queue.

The second challenge in providing statistical guarantees on end-system services is to identify the stochastic nature of the service request arrival process. Many queuing theory results assume a continuous Poisson arrival process. This process is characterized by an exponential distribution of interarrival times. This assumption does not hold for several classes of Internet traffic. For example, research on Web traffic characterization has identified that arrival of Web requests is generally modeled by a heavy tailed distribution (Crovella and Bestavros 1997). One distribution that is commonly used to model request interarrival times and request execution times is the Pareto distribution. Breslau et al. (1999) also determined that URL popularity follows a Zipf-like distribution. This information is important for studies of service performance because it helps quantify the effects of caching. To experiment with Web performance in laboratory testbeds, Barford and Crovella (1998) developed a synthetic Web workload generator that faithfully reproduces the

characteristics of realistic Web traffic, including its heavy-tailed distribution, URL popularity, and reference locality characteristics. The problem of providing queuing-theoretic performance predictions for traffic arriving at a server modeled by the queuing structure outlined above is still an open research topic. Moreover, serving Web requests is only one example of an end-system service. Other services may have distinctly different request patterns that need to be analyzed, understood, and properly modeled.

Relative Guarantees

From queuing theory we know that delay experienced by a request is a function of server load. Ultimately, the only way one can reduce delay to meet deadline guarantees is to keep the load low enough. This implies denying service to some requests under high load to improve performance. In many cases, however, it is preferred that *all* clients receive service when capacity permits. One QoS-provisioning paradigm that subscribes to this model is *proportional relative differentiated services*.

Proportional relative differentiation was first proposed in the networking community in the context of delay differentiation in routers. It was since extended to server end systems. In the relative differentiated services model, it is desired that the ratio between the performance levels of different classes of traffic be fixed; e.g., it may be that the delays of two traffic classes in a network router should be fixed at a ratio of 3:1. In general, if there are multiple traffic classes in the system, and if H_i is the measured performance of class i , the relative guarantee specifies that $H_1: H_2: \dots: H_n = C_1: C_2: \dots: C_n$, where C_i is the weight of class i . Hence, only relative delay between any pair of classes is specified. The absolute delay can take any value. When the system approaches overload, the delay of all classes increases, although some classes see a larger delay increase than others, in accordance with the relative delay guarantee. At present, mechanisms for providing relative delay differentiation are well understood, but not yet deployed.

Relative delay guarantees make the most sense under moderate server load. When the load is light, all classes see identically good service (no delay). When the load is very high, all classes suffer unacceptable delays and timeouts. In general, it is useful to combine relative delay guarantees with absolute delay guarantees in a single framework. The combined architecture bounds the maximum delay of different classes in addition to providing the correct delay ratio when the bound has not been reached. The architecture allows specifying a partial order on absolute and relative time constraints that determines which constraints should be relaxed first when network conditions make the combination unrealizable. Typically, the relative constraints should be relaxed first, hence breaking the performance dependency among the different classes. The performance of more important classes (bound by absolute delay constraints) is then enforced.

Convergence Guarantees

In an environment in which unpredictable traffic conditions make it impossible to satisfy absolute constraints, an

alternative type of performance guarantees has recently been defined. This guarantee views QoS provisioning as a convergence problem and employs control theory to ensure stability and timeliness of convergence of system performance to the right specification (Abdelzaher, Shin, and Bhatti 2002). The statement of the guarantee is that a performance metric, R , will converge within a specified exponentially decaying envelope to a fixed value, called the *set point*, and that the maximum deviation from the set point will be bounded at all times.

The absolute convergence guarantee is translated into a control loop such as those used in industrial control plants. The loop samples the measured performance metric (e.g., delay), compares it to the set point, and uses the difference to induce changes in resource allocation and load. Typically, it performs admission control to reduce load, and reallocates resources to alleviate the bottlenecks.

The use of control theory to control the performance of software processes has gained much popularity in recent years. Traditionally, control theory was used to model and control industrial processes described by difference equations. The intuitive reason that such a theory would be applicable to server performance control is that input load on a server resembles input flow into a water tank. The fill level of the server queue resembles the tank fill level. Admission control resembles a valve on the input flow pipe. Hence, the delay dynamics of a Web server are similar to flow and level control dynamics in a physical plant. The latter are well understood and can be described by difference equations. The second reason that control theory is becoming popular for server control is that feedback control loops are very robust to modeling errors. Hence, accurate models of software dynamics are not needed.

In the context of time-related performance metrics, it is interesting to classify the convergence guarantee loops depending on the performance variable being controlled. As is the case with physical plants, the controlled output of interest affects the model of the system and whether the control loop is linear or not. Because most of control theory was developed for linear processes, the ability to satisfy the convergence guarantee is often contingent on the ability to approximate the server well by a linear model.

To a first approximation, rate metrics and queue length are easiest to control because they result in linear feedback loops. Rate can be controlled in much the same way physical flow is controlled in pipes. Queue length is simply the integral of rate, and therefore is also linear. Delay guarantees are more difficult to provide. This is because delay is inversely proportional to flow. If a request arrives at a queue of length Q , with a constant dequeuing rate of r , the queuing delay, d , of the request is $d = Q/r$. The inverse relation between the manipulated variable (rate) and the delay makes the control loop nonlinear. At present, providing convergence guarantees on delay remains an active research topic.

COMMON CHALLENGES

In the previous section we outlined the semantics of the most important types of performance guarantees and corresponding enforcement mechanisms. Next we

summarize the challenges that are common to achieving these guarantees on end systems.

Admission Control

A common enforcement mechanism of many QoS guarantee types in end systems is client admission control. An important decision in the design of an admission controller is to choose the entity being admitted or rejected. In a typical Internet service, admission control can operate on individual requests, individual TCP connections, or individual client sessions.

Per-request admission control is the simplest to implement, but has serious limitations. Consider an overloaded server operating at 300% capacity. Statistically, this means that two out of three requests must be rejected on average. For simplicity assume that all clients belong to the same class. Client transactions typically feature interactions with multiple requests over the duration of the client's session with the server. Per-request admission control will uniformly cause each client to encounter failures in two thirds of the accesses. All transactions will therefore be affected. Such service will virtually be unusable. In addition to affecting all transactions, per-request admission control discriminates against longer sessions. This has very negative implications, especially from an e-commerce perspective. For example, it has been shown in many studies that those e-shoppers who eventually complete a purchase from an online server typically have longer sessions with the server than occasional visitors who do not buy. Hence, discriminating against longer sessions gives a lower QoS precisely to those users who are more likely to generate revenue.

A better admission control scheme is to select a consistent subset of clients to admit. Those clients are admitted as long as they continue to send requests to the server within a specified time interval. The rest are consistently rejected. This scheme succeeds in making the service usable by at least some consistent subset of clients. It is also more meaningful in the context of addressing attacks on the server, as malicious clients may be tagged for rejection. This scheme is commonly called *session-based admission control*. It was first analyzed at length for Web servers by Cherkasova and Phaal (1999) and continues to be an important research topic (Chen and Mohapatra 2002). Session-based admission control is more difficult than per-request admission control because at the time a session is admitted the server has no knowledge of the future load that it may impose, and whether the client is indeed malicious. Hence, it is difficult to decide how many and which sessions can be admitted. Different clients can impose substantially different load demands. For example, if the admitted client is a Web crawler, it may impose a much larger load than a human user. A mechanism is needed to identify malicious clients. The admission controller must continuously refine the subset of clients to be admitted based on measurements of resulting load and outcomes of authentication.

Rejection Cost

Another issue tightly related to admission control is the cost of rejecting an incoming request. If admission

control is based on client identity (such as his or her encrypted signature) a connection cannot be classified early inside the kernel. Instead, all requests have to reach the application layer, where the server process can interpret the signature and identify the client as belonging to a particular client or class. Now imagine an overloaded server, which decides to admit all requests of class A and reject all requests of class B. Because the kernel cannot tell the two classes apart, all requests are forwarded to the application layer after being processed in the kernel. Kernel processing, as mentioned before, takes a nonnegligible overhead. This overhead is incurred whether the request is accepted or not. In particular, it is incurred for each rejected request. It is therefore called *rejection cost*. For short requests, the rejection cost of the request can be more than half the cost of processing the request successfully. Hence, at overload, a significant portion of server capacity is wasted on request rejection. Rejection cost is therefore one of the primary challenges in improving overload behavior of a server.

Consistent Prioritization

Many guarantee types, such as absolute delay guarantees, usually rely on priority-driven scheduling. Prioritization imposes a significant challenge in most mainstream operating systems. To be effective, all resource queues should be *identically* prioritized. Unfortunately, CPU priorities, which can be set explicitly in many operating systems, control only the order of the ready queue. It has been shown in recent studies that this queue is often not the bottleneck. In a previous section, we have identified at least five resource queues involved in a typical end system. In many cases, the largest queue on the end system is the operating system's listen queue where requests wait on the application server's well-known port. This queue is maintained in the TCP layer and is handled in FIFO order. Correct prioritization would imply prioritizing the socket listen queues as well. In I/O intensive servers, the I/O queue may be the bottleneck. Hence, disk access should be prioritized. Moreover, in a server implementing data structures protected by semaphores, it must be ensured that processes queued on a semaphore are awakened in consistent priority order. Unless all queues are consistently prioritized, it is possible to overload a nonprioritized resource, making that resource the performance bottleneck. Such a load pattern will circumvent any priority differentiation mechanisms employed by other resources to protect high-priority clients, because prioritizing access to non-bottleneck resources has only a marginal effect on performance. For example, if access to disk is not prioritized, a disk-intensive workload may cause high-priority threads to block on disk I/O in a FIFO manner behind a large number of malicious low-priority ones.

Communicating priority information among multiple resources is a nontrivial undertaking. Proper operating system support must exist for priority inheritance across different resources. This support is complicated by the fact that blocking over nonpreemptive resources may cause involuntary priority inversion. The classical example of that is the case of two requests, A and B, where A is of higher priority. Let request B arrive first at some server

and be blocked on a nonpreemptive resource such as a shared data structure protected by a semaphore. Request A arrives later and is blocked waiting for B to release the lock. Meanwhile, the progress of B may be interrupted by an arbitrary number of requests of intermediate priority. In this scenario, A is forced to wait for an arbitrary number of lower priority requests, even when all resource queues (including the semaphore queue) are correctly prioritized. The problem may be solved by the *priority ceiling protocol* developed at CMU, which bounds priority inversion. Unfortunately, current mainstream operating systems neither enforce resource priorities nor implement mechanisms for bounding priority inversion, such as the priority ceiling protocol. Thus, the current state of deployment is far from adequate for the purposes of implementing priority-based QoS support on end systems.

QoS Adaptation

The forgoing discussion focused on controlling load to provide time-related guarantees. The underlying assumption is that service must be provided by the deadline. There are no intermediate compromises. In the following, we present a case for QoS adaptation algorithms, which can negotiate intermediate performance levels within a predefined range deemed acceptable by the user. We describe mechanisms that implement adaptation in end systems.

The Case for QoS Adaptation

Most QoS-sensitive applications have a certain degree of flexibility in terms of resource requirements. For example, JPEG images can be adapted to bandwidth limitations by lossy compression or resolution reduction. Dynamically generated pages can be replaced by approximate static versions to save execution time. Thus, when the server is overloaded, an alternative to rejection of further requests would be to adapt the quality of responses such that the load on the server is reduced. Many leading news and sports sites adopt this policy. For example, the appearance of the Cable News Network Web site www.cnn.com is often significantly simplified upon important breaking news to absorb the higher request rate. An instance of that was the great reduction in CNN site content during the first hours after the attack on the World Trade Center on September 11, 2001.

Content degradation is preferred to service outage for obvious reasons. One is that it maintains service to all clients, albeit at a degraded quality, which is preferred to interruption of service. Another is that it does not incur rejection cost because service is not denied. As mentioned before, rejection cost can be considerable when user-level admission control is used.

To express the flexibility of adaptive applications, an expanded QoS-contract model is proposed. It assumes that the service exports multiple QoS levels with different resource requirements and utility to the user. The lowest level, by default, corresponds to request rejection. Its resource requirements are equal to the rejection cost, and it has no utility to the user. The objective is to choose a QoS level delivered to each user class such that utility is

maximized under resource constraints. QoS adaptation should be used with great care because malicious clients can take advantage of it to artificially degrade server performance to a lower QoS level. Several content adaptation architectures have been proposed in the QoS literature. They can be roughly classified into two general types, depending on the reason for adaptation, namely, adaptation to network/client limitations and adaptation to server load. These two types are described below.

Adaptation to Network and Client Limitations

In the first type, adaptation is performed online and is sometimes called dynamic distillation or online transcoding. For example, see the work of Chandra, Ellis, and Vahdat (2000). The reason for such adaptation is to cope with reduced network bandwidth, or client-side limitations. Note that the dynamic distillation algorithm itself will in fact increase the load on the server. In effect, the algorithm implements a trade-off where extra computing capacity on the server is used to compress content on the fly to conform to reduced network bandwidth. Alternatively, transcoding or distillation proxies may be introduced into the network. For example, a transcoding proxy can identify a client as a wireless PDA device and convert a requested HTML page into WML for display on the client's limited screen.

Adaptation to client-side limitations can also be done using layered services. In this paradigm, content delivery is broken into multiple layers. The first has very limited bandwidth requirements and produces a rough version of the content. Subsequent layers refine the content iteratively, each requiring progressively more resources. JPEG images, for example, can be delivered in this manner. An adaptive service could control the number of layers delivered to a client depending on the client's available bandwidth. A client with a limited bandwidth may receive a fraction of the layers only. The determination of the number of layers to send to the client can be done either by the server or by the client itself. For example, consider an online video presentation being multicast to the participants of a conference call. The server encodes the transmitted video into multiple layers and creates a multicast group for each layer. Each client then subscribes to receive a fraction of the layers as permitted by its resource capacity and network connectivity. Such adaptation architectures have initially been proposed in the context of streaming media.

Adaptation to Server Load

In the second type of adaptation, content is adapted to reduce server load. In this case, dynamic distillation or compression cannot be used because the server itself is the bottleneck. Instead, content must be preprocessed a priori. At run time, the server merely chooses which version to send out to which client. The server in such an architecture has multiple content trees, each of a different quality. For example, a content server can have a full content tree (where data is generated from live database queries), a reduced content tree where some data has been abbreviated or replaced with stale values from

caches, and a low-quality tree that has minimal information. A transparent middleware solution has been described that features a software layer interposed between the server processes and the communication subsystem. The layer has access to the service requests received and the responses sent. It intercepts each request and directs it to the "right" content tree from which it is served. This redirection occurs in accordance with load conditions. To decide on the "right" content tree for each client the interposed content adaptation layer measures the current degree of server utilization and decides on the extent of adaptation that will prevent underutilization or overload.

An interesting question is whether or not load can be adapted in a continuous range when only a small finite number of different content versions (trees) are available. Such continuous adaptation is possible when the number of clients is large. To illustrate this point, consider a server with M discrete service levels (e.g., content trees), where M is a small integer. These levels are numbered $1, \dots, M$ from lowest quality to highest quality. The level 0 is added to denote the special case of request rejection. The admission control algorithm is generalized, so that instead of making a binary decision, it determines a continuous value m , in the range $[0, M]$, which we call the degree of degradation. This value modulates server load in a continuous range. In this case, $m=0$ means rejecting all requests (minimum load), and $m=M$ means serving all requests at the highest quality (maximum load). In general, when m happens to be an integer, it uniquely determines the service level (i.e., tree) to be offered to all clients. If m is a fractional number, composed of an integral part I and a fraction F (such that $m = I + F$), the two integers nearest to m (namely, I and $I+1$) determine the two most appropriate service levels at which clients must be served. The fractional part F determines the fraction of clients served at each of the two levels. In effect, m is interpreted to mean that a fraction $1-F$ of clients must be served at level I , and a fraction F at level $I+1$. The policy can be accurately implemented when the number of clients is large. It ensures that load can be controlled in a continuous range by fractional degradation and offers fine-grained control of delay and server utilization. Figure 3 shows an example of content (an image) with two service levels; regular (Figure 3-a) and degraded (Figure 3-b). In this example, the storage requirements of the degraded image are roughly an order of magnitude less than the requirements of the regular image.

DISTRIBUTED QOS CONSIDERATIONS

Most Internet services are concerned with some form of content or information retrieval. Service performance can therefore be significantly improved by employing proxy servers. A word is thus in order on improving the perceived end-system performance by interjecting proxy services. Proxy servers are intermediaries between the clients and the accessed end-system servers. They are the main performance acceleration mechanism of content retrieval services, which makes their study very important. Interjecting a proxy makes the service distributed. The performance of the service becomes a function of

Figure 3: Example of content degradation (a) regular content (b) degraded content

mechanisms that run both on the origin servers and added proxies. QoS architectures should consider the effects proxy servers have on user-perceived service performance and make use of them to satisfy client QoS requirements. Proxies may be used for caching, transcoding, or content distribution. A proxy intercepts incoming requests and attempts to serve them locally. If the requested content is not locally available the proxy may forward the request to another server (e.g., content distribution proxies), contact the origin server and save the response (proxy caches), or contact the origin server, transcode the response, and forward it to the client (transcoding proxy). Although current proxy servers typically treat all clients alike, there has been much talk on making them QoS-aware. For example, the proxy may offer preferential treatment to some classes of clients or classes of content. QoS considerations that arise in the new distributed architecture of services and their proxies are described below.

Several research efforts have looked at biased replacement policies in proxy caches (Kelly, Chan, Jamin, & Mackie-Mason 1999). Such policies attempt to maximize a weighted hit ratio, where weights are set in accordance with content importance. For example, content fetched from the preferred providers can have a higher weight and therefore a lower likelihood of being replaced. Another research direction is to determine dynamically the disk space allocation of a cache or a content distribution proxy such that content of preferred providers receives a higher hit ratio. In this approach, the “performance distance” between different content types can be controlled (Lu, Saxena, & Abdelzaher 2001). For example, one can specify that preferred content is to receive twice the hit ratio of regular content. The underlying adaptive disk allocation policy uses feedback control to translate this specification into a dynamic disk space allocation that satisfies the specified requirement in the presence of dynamically changing load patterns.

Content distribution networks composed of multiple proxy servers situated around the Internet backbone bring another degree of freedom in distributed QoS provisioning. The distribution provider may make agreements with content providers to distribute their content preferentially for a corresponding fee. Alternatively, the distribution provider may make agreements with certain

ISPs to improve the quality of service to their clients by virtue of the content distribution network. An example of such a network is that introduced by Akamai. When a content provider authorizes a CDN provider to host its content, the CDN could create more than one replica of the content provider’s Web objects on the CDN’s servers. Obviously, the more replicas there are, the better average client access latency can be achieved because chances are clients’ requests can be redirected to a replica closer than the origin server. The actual number of CDN servers hosting a content object is decided by its popularity, the workload conditions of the CDN, and the QoS SLA between the CDN provider and the content provider. Supporting secure content distribution is an attractive feature of CDNs. It is envisioned that in the near future not only content but also “computation” of content providers will be distributed to CDNs. Security concerns have to be carefully addressed before content providers are willing to authorize CDN providers to distribute their sensitive information, such as private data and applications.

CONCLUSION AND FUTURE TRENDS

In this chapter, we briefly introduced the most important issues and mechanisms for providing quality of service in the modern end systems. The topic of providing quality of service guarantees is becoming increasingly important with the pricing of Internet services, and with the tendency to include performance requirements within the contractual obligations of service providers. The need for performance guarantees makes computing systems more vulnerable to attack, since impairing a system’s ability to meet its performance requirements now constitutes a violation of its “proper” functionality. This gives rise to a multitude of QoS mechanisms that must be in place to enforce QoS requirements. In this chapter, some of the most common QoS requirements were reviewed, as well as mechanisms that can be used to enforce them. The chapter also touched on performance considerations that arise in content distribution networks, as well as mechanisms for improving the performance of some essential components of any QoS infrastructure. A particularly

good reference for further readings on Web architecture, performance, QoS, and security issues is the recent book by Krishnamurthy and Rexford (2001).

GLOSSARY

Authentication: The act of verifying client identity.

Backbone provider: A party that owns the communication fabric of an Internet backbone. Examples of backbone providers include AT&T, Sprint, MCI, and UUNET.

Cache server: A network server that acts as a cache of popular Web content and is able to serve it on behalf of the original servers.

Content distribution network: A network of server platforms whose sole purpose is efficient content dissemination around the Internet backbone.

Cookies: Small text files that servers put on the client's hard drive to save client and session information needed for future access.

Data pull model: A data communication model in which the client explicitly asks the server for data each time the data are needed.

Data push model: A data communication model in which servers unilaterally push data to the client without being asked. The model is a good optimization when future client requests can be accurately predicted.

Demultiplexing: Separating an incoming packet flow into multiple segregated flows. For example, demultiplexing must occur upon the arrival of a packet at a server, in order to queue the packet for the right recipient.

Differentiated services: A framework for classifying network traffic and defining different policies for handling each traffic class, such that some classes receive better service than others.

EDF: Earliest-deadline-first scheduling policy. As the name suggests, it schedules the task with the earliest deadline first.

HTML: Hypertext markup language, a language for defining the content and appearance of Web pages.

HTTP: Hypertext transfer protocol. It is the protocol used for Web access in the current Internet. Currently, it has two popular versions, HTTP 1.0 and HTTP 1.1.

IP (Internet protocol): It is the glue that connects the computer subnetworks of which the Internet is composed and is responsible for packet addressing and routing between Internet senders and receivers.

IP fragment: Part of an IP-layer message after fragmentation.

Kernel: The core part of the operating system, typically responsible for scheduling and basic interprocess communication.

Microkernel: An operating system architecture where most operating system functions are delegated to user-level processes, keeping the kernel small.

QoS: Quality of service, a term used in quantifying different performance aspects of Web access such as timeliness and throughput.

Packet: A unit of data transfer across a network.

Persistent connections: Communication abstraction implemented by HTTP 1.1. It allows the same TCP connection to be reused by multiple Web requests to the same server. This is a main departure from the traditional "one request per connection" model of HTTP 1.0.

Proxy server: A specialized server that performs an auxiliary Web content management function such as content replication, caching, or transcoding.

Semaphore: An operating system construct used for synchronization.

Sockets: The main interprocess communication abstraction, originally introduced in UNIX. A socket represents a connection endpoint. The connection is between two processes on the same or different machines.

TCP: Transmission control protocol, the transport protocol used for reliable data communication on the Internet.

Threads: The smallest schedulable entities in multi-threaded operating systems.

Transcoding: The process of converting content on the fly from the server's format to a format more suitable to the client, or more appropriate for network load conditions.

Web hosting: The business of providing resources (servers, disk space, etc.) to serving customers' Web pages. Typically, Web-hosting companies build large server installations of hundreds of machines for serving the Web sites. These installations are called server farms.

INTRODUCTION

Web services refers to an instance of the network services model for distributed computing (Liu 2001). In the network service model (Figure 1), a network application performs all or some of its tasks by making use of ready-made services available on the network.

In such an application, network services can be integrated dynamically, on an as-needed basis. Service providers register themselves with a directory. An application desiring a particular service contacts the directory server at run-time and, if the service is available, will be provided a reference to the service. Using the reference, the application interacts with the service. Java's Jini technology is an example technology that implements this model (Sun Microsystems 2000). This model has been extended to Web services (Figure 2), a technology that initially emerged in 1998 and received public attention by 2002. The World Wide Web Consortium (<http://www.w3.org/>) created the Web services Architecture, Description, and Coordination Groups in January of that year.

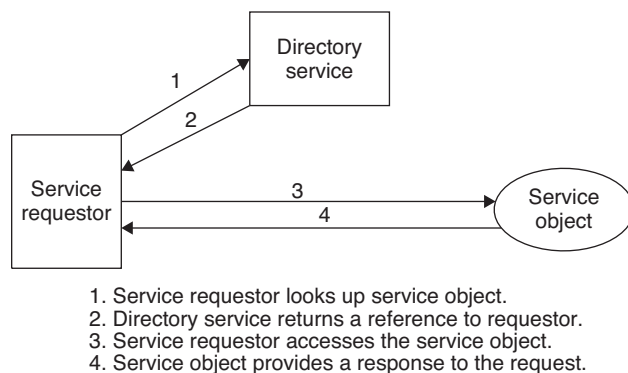

Figure 1: The network services model of distributed computing

Figure 2: The conceptual model of Web services

The popularity of Web services technologies has given rise to the term *service-oriented architecture* (SOA; Channabasavaiah et al. 2003; Weerawarana et al. 2005; Erl 2005) for a software architecture that makes use of reusable services to support the requirements of software users. The implementation of an SOA is typically comprised of individual network-accessible services that are assembled into composite applications. In principle, services in an SOA can be built using any network-access technology. However, open Web services standards that meet cross-platform interoperability requirements for service-oriented computing, such as Web Services Description Language (WSDL), simple object access protocol (SOAP), and universal description, discovery, and integration (UDDI), have gained broad industry acceptance.

The Web services technology provides network services over the World Wide Web, commonly using as transport the basic protocol that is at the heart of the Web: HTTP. The technology has been promoted as a new way to build network applications from distributed components (represented as services), in a language- and platform-independent manner. Since its emergence, the

Web services technology has received widespread attention from the industry, and protocols and tools in support of the technology have proliferated.

WEB SERVICES PROTOCOL HIERARCHY

A Web service is provided by a server object and is accessed by a client. The server and client exchange messages in accordance with standard protocols developed for Web services. Figure 3 depicts the conceptual protocol hierarchy. Logically, the server and client exchange messages at the application layer. Physically, a series of protocols is required to support the message exchange. A service discovery protocol allows the service to be registered and located. The functionalities provided at the service description layer allow a service to be described to the directory. The messaging layer supports the mechanisms for interprocess communication, including the functionalities for data marshaling, and the transport layer delivers the messages. Finally, the network layer represents the network protocol hierarchy for the physical transmission and routing of data packets.

Figure 4 illustrates the typical protocols used for Web services. The standard for service discovery is UDDI, and it includes alternatives such as Web Services Inspection Language (WSIL). The syntax and semantics for services are described using WSDL. The service policy negotiation

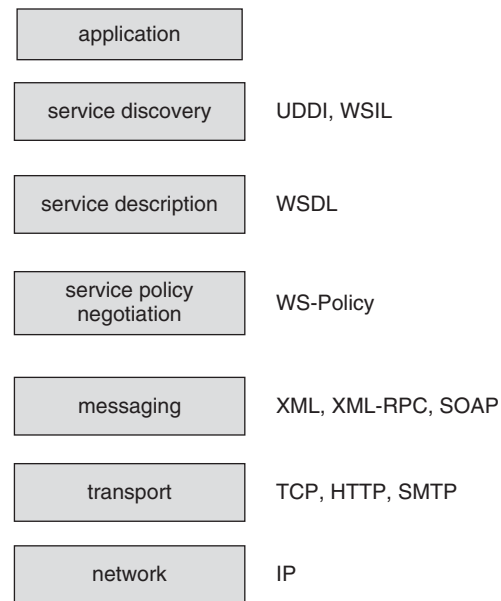

Figure 4: Key Web service protocols

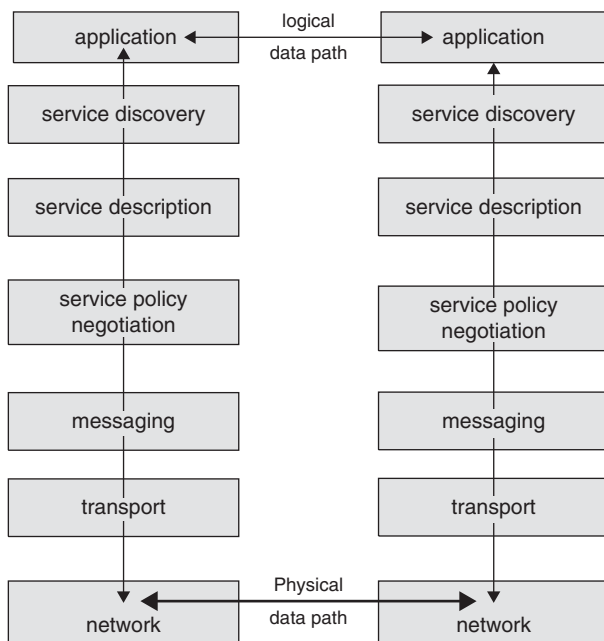

Figure 3: Web service protocol hierarchy

layer allows the client and the service to reach an agreement on which of the various security and messaging options will be employed for the service. The service policy is described using Web Services Policy (WS-Policy) and associated domain-specific policy assertion standards. At the message layer, XML-encoded messages are exchanged according to SOAP. At the transport layer, HTTP transmits the requests and responses; simple mail transfer protocol (SMTP) or Jabber (an instant messaging protocol) transmits messages; and transmission control protocol (TCP) transmits the data. Finally, Internet protocol (IP) serves as the network layer protocol.

WEB SERVICES SOFTWARE ARCHITECTURE

Figure 5 illustrates the software architecture for a Web service. A service listener on the server host listens for service requests transmitted over the Web. When a request is received, it is forwarded to a proxy for the service. The proxy invokes the application logic in the service object and relays the return value to the caller.

Using the Web services architecture, the World Wide Web represents a networked information system hosting resources accessible by service proxy agents. Resources, identified using uniform resource identifiers (URIs), are described, represented, and accessed using a set of standard data formats and protocols.

Figure 5: Web service software architecture

KEY WEB SERVICES TECHNOLOGIES

Following is an overview of some of the key technologies that support Web services. Many recent books investigate these technologies in detail (see Weerawarana et al. 2005; Erl 2005).

XML

XML is a data description language for data sharing among applications, primarily Internet applications, using syntax similar to hypertext markup language (HTML), the language used for composing Web pages. XML allows the use of customized tags (e.g., *message*, *to*, and *from* in Figure 6) to enclose and specify a unit of data contents. XML can be used to facilitate data interchange among heterogeneous systems, to segregate the data content of a Web page (written in XML) from the display syntax (written in HTML), and to allow the data to be shared among applications. Since its introduction in 1998, XML has gained considerable attention and is now widely employed in computer applications

In its basic form, XML is composed of elements, each of which starts with a beginning tag (e.g., `<ELEMENT1>`) that specifies the element name (ELEMENT1, in this case) and a corresponding closing tag (e.g., `</ELEMENT1>`). Many XML-related standards exist, including the XML schema. An XML schema defines the structure, content, and semantics of XML documents, including a hierarchy of elements, attributes, data types, and default values that can appear in a document (W3C Working Group 2004). The use of an XML schema allows XML contents to be validated without requiring a computer application to enforce data compliance. Within the context of Web services, XML is used extensively for service invocations and data sharing.

XML-RPC

XML-RPC is a remote procedure call protocol adapted to the Internet. In XML-RPC, XML-formatted messages are exchanged using the POST request of HTTP. Messages may contain a procedure invocation, a return value, or an error notification.

An example of an XML-RPC request, excerpted from XML-RPC (2006), is presented in Figure 7. An example of an XML-RPC response is presented in Figure 8.

In the procedure call, as well as in the return values, parameters may be data types that include integer, Boolean, string, double, base64, struct, or array. If a procedure call is erroneous, a message containing one or more error codes is returned instead of the return values, as shown in the example in Figure 9.

```
<message>
  <to>MaryJ@BigU.edu</to>
  <from>JohnL@OpenU.edu</from>
  <subject>Interprocess Communications</subject>
  <text>IPC is the backbone of distributed computing ...</text>
</message>
```

Figure 6: A sample XML file

SOAP

SOAP allows messages to be exchanged using object method invocations. Compared to XML-RPC, SOAP is more sophisticated: message composition is constrained by the XML schema, and message validation can be enforced.

The description that follows is a simplified presentation of SOAP messages (W3C Working Group 2004). The protocol is presented in relative detail to illustrate how Web services protocols relate to HTTP.

Figure 10 illustrates the model for SOAP. A Web client issues an HTTP request, whose body contains a message specially formatted for SOAP, which represents a method call to a service object. The request is transmitted to a Web server, which forwards the method call to the named method. The method is invoked. Upon its completion, the value returned by the method is sent to the Web server and then transmitted to the Web client in the body of the HTTP response.

Each SOAP message has a simple format, as depicted in Figure 11.

Each SOAP request is carried in an HTTP request or response, as will be explained in the following section.

A SOAP Request

Figure 12 illustrates the syntax of an HTTP request that carries a SOAP request. The elements of the request are described as follows. Figure 13 highlights the SOAP request extracted from the HTTP request presented in Figure 12. (The example presented in these figures uses a namespace identifier of “m.”)

HTTP Header Lines

The URI in the first line of the HTTP header should specify the object to which the remote method call is directed. In the preceding example, the remote object is */examples*. The User-Agent and Host header lines must be specified.

The Content-Type should be specified as *text/xml*. The charset is a specification of the character representation employed; the default is *US-ASCII*, but another acceptable charset specification is unicode transformation format (UTF). As of SOAP 1.2, the Content-Type can also be *application/soap+xml*. The SOAP-ENV namespace should be mentioned so that it is clear that the SOAP-ENV prefix is bound to the SOAP namespace that defines the XML schema for SOAP messaging. The Content-Length, if specified, should be the byte length of the request body.

The SOAPAction header line specifies the remote object to which the request is to be directed. The interpretation of this header element is up to the program. In most cases, the URI (specified in the first header line) and the SOAPAction header will have the same value.

HTTP Body

The HTTP body contains a SOAP envelope. Each SOAP envelope in turn contains an optional SOAP header and a required SOAP body.

SOAP envelope. The SOAP envelope is defined with the `<SOAP-ENV:Envelope>` element, which contains a set of required attributes. These attributes specify the encoding

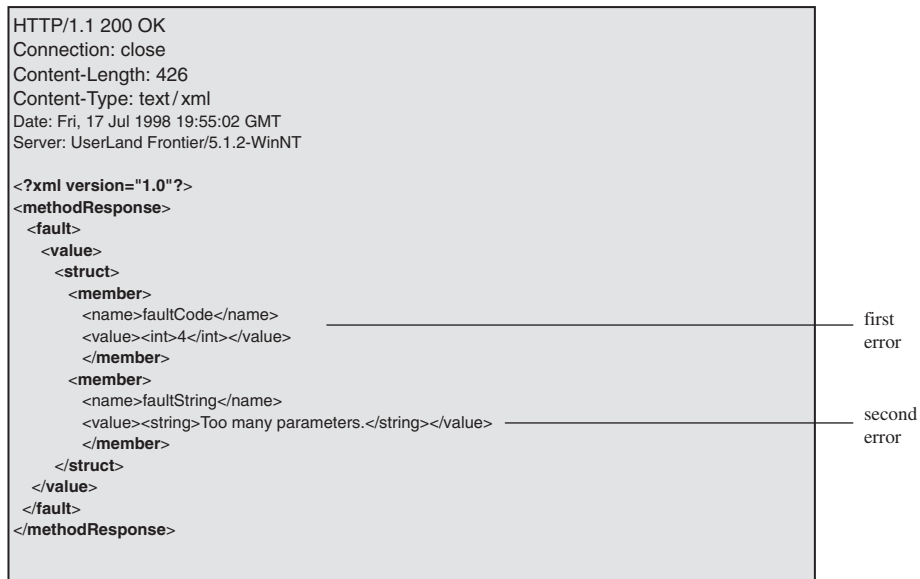

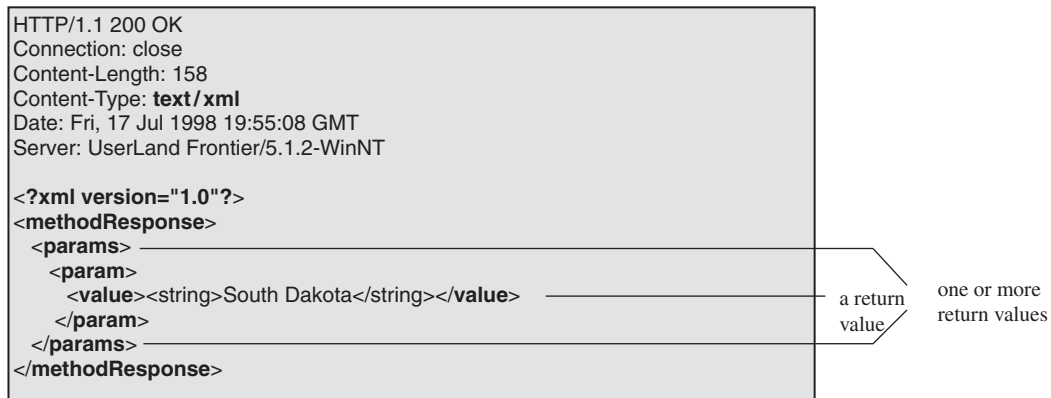

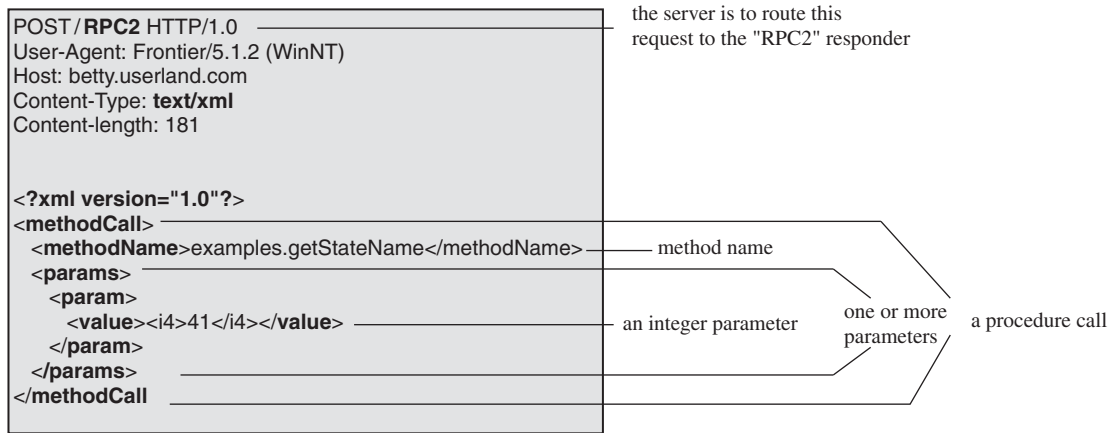

Figure 7: An example XML-RPC procedure call message (XML.RPC 2006)

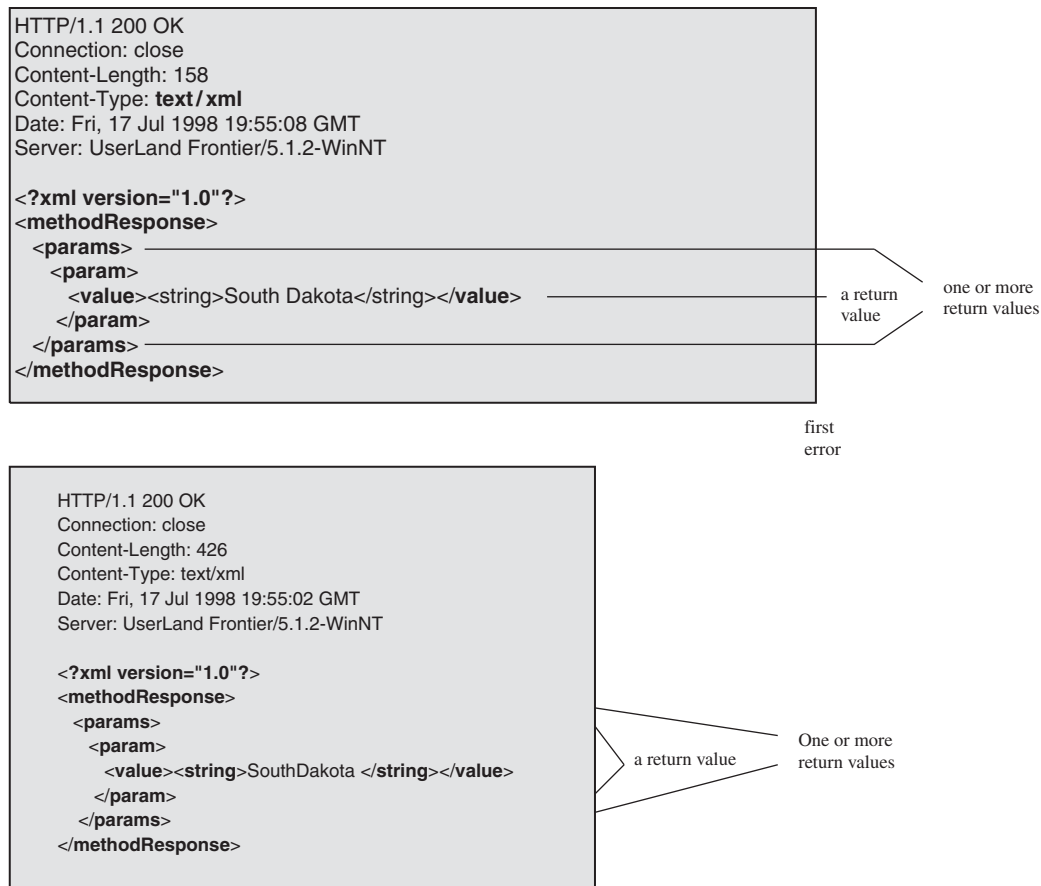

Figure 8: An example XML-RPC return values message (XML.RPC 2006)

scheme and envelope style; the syntax is not dependent upon the method call. The *xmlns:soap-env* attribute specifies the namespace that defines the XML schema for SOAP messaging.

SOAP header. The SOAP header is optional. It is defined with the *<SOAP-ENV:Header>* element. The header element provides meta-information specific to the request. Examples of such information include:

- Protocols that the server is expected to understand
- A digital signature for the body of the message
- A schema for the XML application used in the body
- Credit card information to pay for the processing of the request
- A public key to be used to encrypt the response

SOAP body. The SOAP body is defined with the *<SOAP-ENV:Body>* element. The SOAP body contains a single element, which represents the procedure call. The name of the procedure is the name of this element (e.g., *getStateName*). The elements contained within the procedure call are the parameters to the procedure, if any exist. The names of the parameters are significant, but the order of the parameters is not. Parameter data type is indicated by the *xsi:type* attribute, which will be described later on in the chapter.

Data Types

SOAP contains a rich set of language-independent data types that are based on XML schema data types. The table in Figure 14 summarizes a subset of the key scalar data types supported by SOAP 1.1; nonscalar data types including structs, arrays, objects, vectors, and enumerations are also supported in SOAP.

SOAP response. Figure 15 shows an HTTP response that contains a successful SOAP response. The header follows the usual format. Note that the content type is *text/xml*.

Figure 16 highlights the SOAP response extracted from the HTTP response presented in Figure 15. As with the SOAP request, the response is composed of two parts: the envelope and the body. (The example presented in these figures uses a namespace identifier of “m.”) The syntax for the envelope is the same as for the request. The syntax for the body, highlighted in Figure 16, is also analogous to that of the request.

The single element contained in the *<SOAP-ENV:Body>* has a name that must match the name of the method that was called, with “*Response*” attached to the end of the method name. The data type and value of the returned value are contained in the Result subelement.

A SOAP method call may fail, perhaps due to an erroneous method name or a bad parameter passed. When a method call cannot be completed successfully, the HTTP

response (see Figure 17) contains a SOAP body that defines a fault code and a fault string. The fault code (SOAP-ENV: Client) identifies the fault, and the fault string provides a description of the fault.

REST

Representational state transfer (REST) is an architectural style for distributed hypermedia systems (Fielding 2000) that has received wide acceptance among Web application developers. REST focuses on the nature and state of a system's data elements. These data elements have a shared understanding of data types (using metadata) but limit the scope of what is revealed to a standardized interface. REST components communicate by transferring a representation of a resource, such as a Web service, in a format selected dynamically based on the capabilities or desires of the recipient and the nature of the resource. Using REST, each procedure or method call of remote procedure call (RPC) and SOAP may instead be represented as a separate resource identified by its own URL, resulting in a simplified user interface for accessing the service. REST has been touted as the technology for second-generation Web services (Prescod 2002).

WSDL

WSDL 2.0 (W3C Working Group 2004) is a language used to describe Web services. For each service, WSDL can be used to describe the messages that are exchanged between the requester and provider, and the operations exposed for accessing the service.

Web service definitions can be mapped to any implementation language, platform, object model, or messaging system, as long as both the service requester and the service provider agree on the service description. This provision allows Web services to be implemented for interaction via browsers, or directly within an application implemented using any language/technology that understands WSDL.

Figure 18 presents a sample WSDL file that describes a Web service for hotel reservations. A detailed explanation

```

HTTP/1.1 500 Server Error

of the WSDL syntax and semantics is available from the W3C Working Group (2004).

UDDI

The UDDI protocol was set forth by OASIS (UDDI 2006; OASIS 2004); it defines a standard for publishing and discovering the network-based software components of a service-oriented architecture. UDDI creates a standard interoperable platform that enables Web clients to dynamically discover and make use of Web services, and it allows service directories to be maintained independent of the purposes and contexts of diverse applications.

The UDDI protocol makes use of XML, HTTP, domain name system (DNS), and XML protocol messaging. Detailed description of the protocol and an explanation of its usage can be found in Chappell and Jewell (2002).

```

Figure 18: A sample service description in WSDL (W3C 2004)

USING WEB SERVICES

Steps

The World Wide Web Consortium (W3C Working Group 2004) specifies four steps involved in the process of engaging a Web service:

1. The service requester and provider entities make contact with each other. In a typical case, the requester initiates the interaction in one of two ways: (1) the requester obtains the provider's address directly from the provider entity; or (2) the requester may use a discovery service to obtain the address of a suitable service description. The discovery may be manual or through autonomous selection, and it is accomplished using a functional description of the service. Less typically, the provider initiates the interaction by obtaining the address of the requester in some way.
2. The requester and provider reach an agreement on a policy alternative per WS-Policy.
3. The requester and provider implicitly or explicitly reach an agreement on the description and semantics of the service in one of the following ways:
 - The requester and provider may communicate directly with each other to explicitly agree on the service description and semantics.
 - The provider may publish the service description and semantics.
 - The service description and semantics (except the network address of the particular service) may be defined as a standard by an industry organization.
 - The service description and semantics may be defined and published by the requester entity and offered to a potential provider as a solicitation for the service.

4. The requester and provider implement the service and exchanges according to its description and semantics. The implementation may be carried out in many ways, including:
 - A service may be hard coded to implement a specific, static service description and semantics.
 - A service may be coded in a general way that allows the desired service description and/or semantics to be input dynamically.
 - The service description and/or semantics may be generated dynamically by an agent created to provide the service.
5. The requester and provider exchange requests and responses for the service.

Development Environments

A large number of tools and systems have been developed by a multitude of organizations to facilitate the building of Web services and clients. These tools and systems provide abstractions to allow a developer to focus on the logic at the highest layer of the protocol stack. Following is a list of such tools and systems. (Note: this list is not comprehensive.)

- The Apache Software Foundation (<http://www.apache.org/>) has a Web services Project that provides a toolkit for XML-RPC. The Apache XML-RPC toolkit features a set of Java classes for Web service servers and clients.
- The Apache Software Foundation has another product known as Apache Axis (<http://ws.apache.org/axis/>), which supports SOAP-based Web service servers and clients written in Java.
- The Java Web services Developer Pack (Java WSDP) by Sun Microsystems, now dubbed the Java XML Web services (JAX-WS) open-source project, provides a Java application programming interface (API) that supports Web services (Sun Microsystems 2006).
- The IBM Web services toolkit (WSTK), now known as the Emerging Technologies Toolkit (ETTK) for Web services and Autonomic Computing (ETTK-WS), also provides an API for Web services development (alpha-Works 2006).
- Microsoft's .NET Framework provides Web services support (Shodjai 2006) via Visual Studio.
- The Web services interoperability (WSI) site, <http://www.ws-i.org/>, provides implementation guidelines for how related Web services specifications should be used together for best interoperability. It also provides testing tools and sample Web services applications.
- SoapClient (<http://www.soapclient.com/>) is a site that hosts links to a repertoire of useful resources, including (1) a generic SOAP client that allows one to execute SOAP services using a Web browser, and (2) a SOAP interoperability test that defines a set of standard methods that can be invoked for testing interoperability of Web services.
- Xmethods (<http://xmethods.net/>) provides a repository that houses Web services contributed from third parties and available for free access. The site also

includes links to tools and tutorials of interest to software developers.

WEB SERVICES STANDARDS

Because interoperability is an inherent goal for Web services, the architecture has prompted intense efforts in standardization.

Standards Organizations

Industry vendors have participated in the Web services standardization process under the sponsorship of various consortia, including the following three key organizations:

1. The World Wide Web Consortium (W3C; <http://www.w3.org/>): The W3C released XML 1.0 in 1998 and is the originator of the specifications of HTTP, HTML, SOAP, and WSDL. The W3C is also responsible for a number of XML-based specifications: XML encryption, XML XSL (extensible stylesheet language), XSL transformations (XSLT), XPath, and XQuery. Currently, WS-Policy and WS-PolicyAttachment are being standardized by the W3C.
2. The Organization for the Advancement of Structured Information Standards (OASIS; www.oasis-open.org): OASIS specifies standards that enable specific business or IT functionality, including standards that cover business aspects (e.g., security, transaction support, and management). Standards developed by OASIS relevant to Web services include UDDI, WS-ReliableMessaging (WS-RM), Web services resource framework (WSRF), Web services security (WS-security) and Web services transaction (WS-TX).
3. The Web Services Interoperability Organization (WS-I; www.ws-i.org): WS-I promotes interoperability between Web services product implementations. WS-I is best known for its guidelines of interoperability specifications for the core set of Web services standards: WSDL, UDDI, and SOAP. The best known of such guidelines is WS-I BasicProfile. WS-I has also released a variety of tools for conformance testing.

WS-* Standards and Proposals

A plethora of WS-prefixed standards and proposals have been developed by the aforementioned standard organizations and other entities. These specifications are in a state of flux. Following is a nonexhaustive enumeration of these standards and proposals:

- WS-Addressing: used to address Web services and messages
- WS-Agreement: used for service-level agreements between Web services in a grid environment
- WS-AtomicTransaction: provides the definition of the atomic transaction coordination type that is to be used with the extensible coordination framework described in the WS-Coordination specification

- **WS-Attachments:** encapsulates a SOAP message and zero or more attachments; this work has been rendered obsolete by the SOAP message transmission optimization mechanism (MTOM) specified by the W3C
- **WS-BusinessActivity:** provides the definition of the business activity coordination type that is to be used with the extensible coordination framework described in the WS-Coordination specification
- **WS-Coordination:** provides protocols that coordinate the actions of distributed applications
- **WS-Discovery:** defines a multicast discovery protocol to locate services
- **WS-Enumeration:** extends the single-request/single-reply in basic SOAP to allow a data source to provide a session abstraction, called an enumeration context, to a consumer
- **WS-Eventing:** allows a Web service to receive messages when events occur in other services and applications
- **WS-Federation:** defines mechanisms to allow different security realms to federate using different or like mechanisms by allowing and brokering trust of identities, attributes, and authentication between participating Web services
- **WS-Inspection:** specification provides an XML format for assisting in the inspection of a site for available services and a set of rules for how inspection-related information should be made available for consumption
- **WS-Manageability:** defines the manageability interface for the Web services end point based on the general concepts of a manageability model in terms of manageability topics (identification, configuration, state, metrics, and relationships) and the aspects (properties, operations, and events) used to define them.
- **WS-MetadataExchange:** defines a standard mechanism for metadata-driven message exchange
- **WS-Notification/WS-Topics:** define a standard approach to notification using a topic-based publish/subscribe pattern
- **WS-Policy:** provides a general purpose model and syntax for expressing the capabilities, requirements, and general characteristics of entities in an XML Web services-based system
- **WS-Provisioning:** describes the APIs and schemas necessary to facilitate interoperability between provisioning systems and to allow software vendors to provide provisioning facilities in a consistent way
- **WS-ReliableMessaging:** describes a protocol that allows messages to be delivered reliably between distributed applications in the presence of software component, system, or network failures
- **WS-ReliableMessaging Policy:** defines policy assertion formats for reliable messaging in conjunction with WS-Policy
- **WS-Resource Framework:** defines a family of specifications for accessing stateful resources using Web services
- **WS-SecureConversation:** defines secure conversation assertion formats for security in conjunction with WS-Policy

- **WS-Security:** describes enhancements to SOAP messaging to provide quality of protection through message integrity, message confidentiality, and single message authentication
- **WS-SecurityPolicy:** defines policy assertion formats for security in conjunction with WS-Policy
- **WS-Transfer:** defines a mechanism for acquiring XML-based representations of entities using the Web service infrastructure

WEB SERVICES SECURITY

The interoperable nature of Web services gives rise to special concerns about security. Security threats involve the systems that host Web services, the applications that deploy the services, and the underlying network infrastructure.

Security Requirements

The W3C Working Group (2004) lists the following requirements for providing end-to-end security for Web services:

- Authentication mechanisms for verifying the identities of the requester and provider agents.
- Authorization mechanisms for controlling requester access to appropriate system resources. Policies based on the principle of least privilege access may be used to determine the access rights of a requester to systems and their components.
- Data integrity mechanisms to ensure that information has not been altered during transmission. Data confidentiality ensures that the data are only accessible by the intended parties. Data encryption and digital signatures are techniques that can be used to implement these mechanisms.
- Integrity of transactions and communications mechanisms to ensure that the business process and work flow conducted on behalf of the Web service is performed properly.
- Nonrepudiation mechanisms that provide evidence about the occurrence of a transaction. This protects a party to a transaction against false denial of the occurrence of that transaction by another party.
- End-to-end integrity and confidentiality of messages must be ensured even in the presence of intermediaries.
- Audit trails to allow tracing of user access and behavior, and to ensure system integrity through verification.
- Distributed enforcement of security policies across various platforms with varying privileges.

Security Consideration of the Web Services Architecture

The W3C Working Group (2004) further specifies the following Security Consideration of the architecture for Web services:

Organizations that implement Web services must be able to conduct business in a secure fashion. All aspects of Web services, including routing,

management, publication, and discovery, should be performed in a secure manner. Web services implementers must be able to utilize security services such as authentication, authorization, encryption, and auditing.

Web services messages can flow through firewalls and can be tunneled through existing ports and protocols. Web services security requires the use of appropriate corporate-wide policies that may need to be integrated with external cross-enterprise policy and trust resolution. Organizations may need to implement capabilities that include:

- **Cross-domain identities:** Requester and provider agents may communicate with each other using various identity verification schemes from different security domains. It is important for Web services to be able to support the mapping of identities across multiple domains and even within a single domain.
- **Distributed policies:** Security policies should be available to define the access privileges of requests and responses between parties.
- **Trust policies:** Trust policies should be available to allow the requester to trust the environment of a service and the provider to trust the environment of the requester entity.
- **Secure discovery mechanism:** Secure discovery mechanism should be in place to enforce policies that govern the publication and discovery of a service, thus allowing a service to selectively provide an identity only to trusted requesters.
- **Trust and discovery:** Provisions should be made to allow a judgement to be made by a requester with respect to whether a service discovered can be trusted.
- **Secure messaging:** Secure messaging ensures privacy, confidentiality, and integrity of interactions. The digital signatures techniques can be used to help ensure nonrepudiation. Techniques that ensure channel security can be used for securing messages. Message security techniques such as encryption and signing of the message payload can be used in routing and reliable messaging.

Web Services Security Technologies

Web services technologies are based on the aforementioned WS-Security standard. The W3C Working Group (2004) cites the following technologies available for Web services security:

XML-Signature: XML-Signature, jointly developed by W3C and the Internet Engineering Task Force (IETF), is designed for use in XML transactions. This standard defines a schema for capturing the result of a digital signature operation applied to arbitrary data and their processing. XML-Signature has the ability to sign only specific portions of the XML tree rather than the complete document, thus allowing a single XML document to be signed multiple times by a single or multiple parties. This flexibility can ensure the integrity of certain portions of an XML document while leaving open the possibility for other portions of the document to change.

XML-Encryption: XML-Encryption specifies a process for encrypting data and representing the result in XML. The data may be arbitrary data (e.g., an XML document), an XML element, or XML element content.

Web Services Security: Web Services Security (WSS) defines a SOAP extension that provides message integrity, confidentiality, and authentication.

WSS provides a general mechanism for associating security tokens with messages. The specification defines an end-to-end security framework that provides support for intermediary security processing. Message integrity is provided by using XML-Signature in conjunction with security tokens to ensure that messages are transmitted without modifications. The integrity mechanisms can support multiple signatures, possibly by multiple actors. The techniques are extensible such that they can support additional signature formats. Message confidentiality is granted by using XML-Encryption in conjunction with security tokens to keep portions of SOAP messages confidential.

XML Key Management Specification: The XML Key Management Specification (XKMS) is an XML-based way of managing the public key infrastructure (PKI), a system that uses public key cryptography for encrypting, signing, authorizing, and verifying the authenticity of information on the Internet. It specifies protocols for distributing and registering public keys, suitable for use in conjunction with the proposed standard for XML-Signature and XML-Encryption.

XKMS allows implementers to outsource the task of key registration and validation to a “trust” utility. This simplifies implementation because the actual work of managing public and private key pairs and other PKI details is done by a third party.

An XKMS trust utility works with any PKI system, passing the information back and forth between it and the Web service. Because the trust utility does the work, the Web service itself can be kept simple. XKMS is a W3C specification.

Security assertion markup language: Security assertion markup language (SAML) is an XML-based standard for exchanging authentication and authorization data between a service provider and a client. SAML is useful for providing single sign-on.

The three basic SAML components are assertions, protocol, and binding. An assertion can be one of many types, including authentication, attribute, and authorization. Authentication assertion validates the identity of the user; the attribute assertion contains specific information about the user; and the authorization assertion identifies what the user is authorized to do.

Extensible access control markup language: Extensible access control markup language (XACML) is an XML-based technology for supporting distributed access control policies.

XACML includes an access control language along with a request/response language that allows policies to be written to control users’ access. XACML has been integrated with SAML so that the SAML query and response protocol can be used with an XACML policy engine

consuming XACML policies, and SAML can be used to transmit XACML artifacts (e.g., requests, responses, policies, attributes) securely over the Web.

Identity federation: Federated network identity is the notion that businesses or organizations can be affiliated into circles of trust and trust relationships.

The Liberty Alliance (<http://www.projectliberty.org/>) project was established to develop an open standard for federated network identity through open technical specifications. The Liberty specifications make extensive use of XML, including the use of SAML for simplified sign-on. Their work is grouped into three categories: identity federation framework (ID-FF), identity Web services framework (ID-WSF), and identity service instance specifications (ID-SIS; Liberty Alliance Project 2006).

ID-FF focuses on human-to-application interactions and has been integrated with SAML 2.0; ID-WSF focuses on application-to-application interactions in a Web services environment; and ID-SIS specifies particular identity-based services. Following is a summary of the three categories.

A separate effort in identity federation is WS-Federation by IBM and Microsoft, created as part of their proposal for a Web services security framework (WS-Security). The WS-Federation framework includes three components: (1) the Web Services Federation Language, which defines how different security domains broker identities, user attributes, and authentication between Web services; (2) Passive Requestor Profile, which describes how a federation provides identity services to Web browsers, Web-enabled cell phones, and devices; and (3) Active Requestor Profile, which describes how a federation provides identity services to applications such as those based on SOAP (Network World 2006).

INDUSTRIAL ACCEPTANCE OF WEB SERVICES

The concept of Web services has strong appeal to the industry. Major companies, including Microsoft, IBM, and Sun Microsystems, have promoted Web services. Microsoft in particular has significant involvements in the development of Web services standards and at one time had an ambitious plan for delivering consumer Web services. Although the industry shows interest in expanding Web services, the research firm IDC reported in 2002 that full-scale adoption could be at least a decade away (Dignan 2002). A somewhat recent ComputerWorld article (2004) stated that Web services have yet to enjoy their predicted widespread adoption, and Web services technology has yet to be embraced by the broader IT and economic climate because its deployment does not generally reduce costs.

Gartner Research (Cantara 2006) reported that, based on surveys conducted at SOA conferences held in 2005 and 2006, "spending on SOA and Web Services as a percent of IT Budget . . . increased from 11% in spring 2005 to 18% in June 2006. Conference attendees expect to spend 22% of their IT budgets on SOA, Web Services, and Web 2.0 in 2007."

Web services are now employed by many enterprises to link internal business systems and exchange data with other companies. Online sites now commonly make use of Web services offered by major companies, such as those listed below, to provide customer support (e.g., price comparison and shipment tracking).

Amazon.com (2006): The online bookseller has provided a Web service that allows client applications to browse its product catalog and place orders.

FedEx (2006): The shipping company has provided a FedEx API Client Libraries interface for Windows, Solaris UNIX, and LINUX clients to issue a remote procedure call as a FedExAPI transaction to the FedEx Internet server. Using the mechanism, a client may retrieve tracking information for packages.

eBay (2006): eBay supports Web services that provide easy access to the eBay marketplace. The Web services support communication directly with the eBay business logic and database, allowing customized applications for item sales management, inventory systems, item search, user account management systems, partner item listings, and buyer's managing of listings of interest. According to Chappelle (2004), in 2004 over 40 percent of eBay's listings came through the E-Bay Web services API calls.

eBay provides multiple software developer kits (SDKs) for using the API, allowing applications to be developed in most popular languages.

Google (2006): The search engine provider is giving developers direct access to its search database, bypassing its Web site and allowing them to design their own ways to use Google's search engine technology. Google supplies a downloadable developer's kit that allows developers to use Google's service to "query billions of Web pages directly from their own computer programs" (Google 2006). A sample Java program and .NET program that make use of the service can be found on the download site at <http://www.google.com/apis/download.html>.

Microsoft (2006): Microsoft offers a MapPoint Web service for use by enterprises and independent software developers to "integrate location-based services, such as maps, driving directions and proximity searches, into software applications and business processes" (Microsoft 2006). According to Microsoft, the MapPoint Web service currently supports more than 15 million transactions daily.

WEB SERVICES ACCESS FROM MOBILE DEVICES

A promising growth area for Web services is applications deployed on mobile platforms. However, mobile devices such as cell phones typically do not come with built-in Web services support for processing HTTP commands and XML requests. Even if they do, performance is a concern. A proxy may be used to serve as an intermediary between the mobile device and the Web service provider (Elkarra 2003).

Some of the most promising technologies in this arena are described as follows.

Java ME

The Java Micro Edition (Java ME) is one of the most widely used application platforms for mobile devices such as mobile phones, personal digital assistants (PDAs), TV set-top boxes, and printers. The Web services API (WSA) for Java ME comprises two optional packages:

- The XML processing package is based on the Java API for XMP Processing (JAXP) and on the Simple API for XML (SAX).
- The API for remote Web services invocation is a subset of the Java API for XML-Based RPC (JAX-RPC) specification.

To support platform independence, WSA uses a stub as a proxy between the application and the mobile service provider interface. The architecture is depicted in Figure 19.

VoiceXML

VoiceXML (W3C Working Group 2000) is an extensible markup language with which Web services can be provided to customers with voice interfaces on devices such as the telephone, specifically cell phones.

Accessing Web services with VoiceXML (2006) is facilitated by the use of tools such as BeVocal's JavaScript SOAP API (2006). The BeVocal Cafe offers a phone number that a user can call to access a voice-interfaced Web service.

The Tellme Networks Inc. (2006) offers a Tellme service that provides, among other things, voiced driving directions using Microsoft's MapPoint Web service (Microsoft 2006). Tellme Inc's Studio also offers a development environment for developing VoiceXML applications. Tellme does not support RPC directly but can be coupled with a Web service to generate VoiceXML output to the client. For example, Tellme's Notifier service allows a VoiceXML application to initiate phone calls to clients. The Notifier

service can also be used to deliver reminders of appointments and other voice messages.

Microsoft's .NET Compact Framework

The .NET Compact Framework provides an environment for developing mobile applications using the traditional Microsoft point-and-click interface.

The .NET Compact Framework is a subset of the .NET Framework and is designed specifically to provide support for Web services. The .NET Compact Framework is available for devices running the Microsoft Windows CE operating system. Compact Framework applications can be developed using Visual Studio.NET, VB.NET, and C#. A sample Web service and client can be found in Microsoft (2003).

RELATED TECHNOLOGIES

The following technologies, though noteworthy, are beyond the scope of this article:

1. Web service interaction protocols: One of the most promising applications of Web services is their use to support business processes that involve complex interactions. A host of Web services standards have been created to support such business processes (e.g., WS-transaction, Business Process Execution Language [BPEL], and Web Service Choreography Description Language [WSDL]). Readers are referred to Weerawarana (2005) for details.
2. The application of semantic Web: Semantic tagging of the Web promises to bring dramatic changes to the cyber world. Once the semantics of Web services descriptions can be interpreted and understood by computers, the automatic discovery and composition of Web services will be much more powerful than the current approach (e.g., UDDI). Among the noteworthy emerging semantic Web services description protocols is the Ontology Web Language—Service (OWL-S)

Figure 19: The Architecture of Web Services APIs (WSA) for Java ME

ontology standard. Readers are referred to Alesso and Smith (2004) for details.

CONCLUSION

The service-oriented architecture in general and Web services in particular hold great promise for networked applications.

Web services technology has received widespread attention from the information technologies (IT) community and computing industries, and has spawned a plethora of protocols and supporting technologies.

This chapter has provided an overview of the Web services technology and its underlying architectures and protocols. The key supporting protocols, including XML, XML-RPC, SOAP, WSDL, and UDDI, were presented, and the steps and tools for deploying Web services were explained. Also presented were the standards, the security concerns and technologies, and the current state of industrial acceptance of Web services.

Although Web services technology has attracted widespread attention, it has yet to fulfill its promise as a mainstream IT technology. Some of the major hurdles that the technology must overcome include security concerns, reliability, and performance. The overwhelming number of standards that have been developed by diverse organizations poses another challenge: sorting out these standards and ensuring their interoperability is a daunting task.

For now, the technology has found acceptance in Web-based commercial sites such as eBay, Amazon, and Google, which support direct access by the customer to the organization's business logic and database. The technology has also made headway on mobile platforms.

GLOSSARY

HTTP: Hypertext transfer protocol, the basic protocol that supports the transport of data over the World Wide Web.

OASIS: Organization for the Advancement of Structured Information Standards (www.oasis-open.org).

Service-Oriented Architecture (SOA): Software architecture that makes use of reusable services to support the requirements of software users.

SOAP: Simple object access protocol.

UDDI: Universal description, discovery, and integration.

W3C: The World Wide Web Consortium (<http://www.w3.org/>).

Web Services: Network services provided over HTTP.

WSDL: Web Services Description Language

WS-I: The Web Services Interoperability Organization (www.ws-i.org).

XML: Extensible markup language

XML-RPC: a remote procedure call protocol adapted to the Internet

INTRODUCTION

A mobile cellular system (Jakes 1974; Rappaport 2002) consists of base stations and mobile stations; the latter are also called *terminals*. The mobile stations communicate with each other through the base stations. Each mobile station uses a two-way wireless radio channel dedicated to it. The base stations usually communicate with each other through optical fibers. The area around a base station where communications with the base station are possible is called a *cell*. Thus, a set of base stations forms a *cellular system*, which ideally covers the whole world. The cells are partially overlapping so that continuous communications are possible when a mobile station moves from one cell to another. A handover is made when the cell is changed.

We will present an introduction to the cellular communications channels between a base station and a mobile station. The link between a base station to a mobile station is called a *downlink*. The link between a mobile station to a base station is called an *uplink*. Usually, the downlink and uplink are separated by using different frequencies. Nearby base stations must also use different frequencies to avoid interference. Frequencies for cellular systems are a scarce resource that must be efficiently used and the frequencies must be reused. In a typical reuse cluster, there are seven approximately hexagonal cells: the cell of interest and its six surrounding cells. All cells in the same cluster use different frequencies, and the corresponding cells in the other clusters reuse the same frequencies. The reuse is possible because the radio waves are attenuated when they are broadcasted in many directions and partially absorbed by the intervening medium. The interference can be further reduced if in a base station a cell is split into three sectors by using narrow-beam antennae.

Cellular communications channels are fundamentally different from wired ones. The quality of the channels changes rapidly as a function of time, frequency, and location or space when the users of the mobile stations are moving. These changes in quality propagate to higher protocol layers—that is, to the data-link layer and the network layer. Understanding the characteristics of

the channels is paramount to the successful design of wireless networks.

The main emphasis in this chapter is on channel models for radio wave propagation in terrestrial outdoor mobile cellular systems in either microcells or macrocells. Most contemporary cellular systems, such as the *global system for mobile communications* (GSM), *enhanced data rates for GSM evolution* (commonly referred to as EDGE), *cdmaOne*, *CDMA2000*, and *universal mobile telecommunications system* (UMTS), typically work in the frequency range from approximately 1 GHz to 2 GHz with the corresponding wavelengths between 0.3 m and 0.15 m (the abbreviation CDMA refers to *code division multiple access*). The bandwidth of the transmitted signals is on the order of 100 kHz to 5 MHz. The fourth-generation systems that will be used in the 2010s are envisioned to use carrier frequencies as high as 5 GHz and 10-MHz to 100-MHz signal bandwidths. The velocity of a terminal can vary from the walking speed of approximately 5 km/h up to the maximum speed of trains, or from 250 km/h to 500 km/h.

The location of the base station antenna has a significant effect on channel modeling. In *microcells*, the cell radius is approximately 0.1 km to 1 km, and the base station antenna is below the rooftop level of the surrounding buildings. On the other hand, in *macrocells* the base station antenna is above the rooftop level, and the cell radius is approximately 1 km to 30 km. The area types are usually divided into *urban*, *suburban*, and *rural*, each of which may be nonhilly or hilly.

A radio channel is almost always linear (Bello 1963) (see Figure 1). Because of mobility, the channel is also time variant. The received signal is attenuated because of the path loss from the radio waves propagating in all directions and being partially absorbed by the intervening medium. Fading can be caused by shadowing when the propagation environment is changing significantly so that the path loss is changed randomly. This fading is typically much slower than the multipath fading caused by multipath propagation. Modem design is mainly affected by the faster multipath fading (Stein 1987), which can be normally assumed to be locally *wide sense stationary* (WSS).

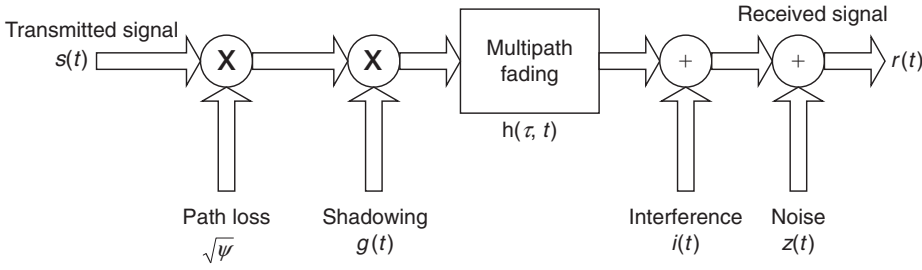

Figure 1: Several parts of the channel model

Thus, in many cases, only the multipath fading needs to be analyzed or simulated. The signal is also corrupted by additive noise and interference.

The chapter is organized as follows. First, we present the complex envelope of real bandpass signals. Second, we give a statistical description of one- and two-dimensional channel models. Third, we summarize the methods by which the channel is measured. Fourth, we describe widely available simulation models, and then we conclude by noticing recent trends in cellular communications channels. More extensive reviews are included in Pahlavan and Levesque (1995) and Rappaport (2002) for the one-dimensional models and in Ertel et al. (1998) for two-dimensional models. Models for indoor communications are summarized in Hashemi (1993). Much of the theory is valid also for outdoor communications. Our list of references is not exhaustive, and important work has been left out because of space limitations. Additional references can be found from the books and papers cited. We assume that the reader knows the basics of linear systems including the Fourier transform. All of the necessary information can be found from Haykin (1983).

COMPLEX ENVELOPE MODEL OF REAL BANDPASS SIGNALS

All signals that appear in nature are real. To make mathematical equations compact and simulations efficient, we use the *complex envelope* (Haykin 1983; Proakis 2001) or the low-pass equivalent model $s(t)$ of the actual real bandpass signal $s_B(t)$, which are both functions of time t . A bandpass signal $s_B(t)$, whose bandwidth is assumed to be $W < f_c$ where f_c is the carrier frequency, can be represented in two equivalent forms:

$$\begin{aligned} s_B(t) &= a(t) \cos[2\pi f_c t + \theta(t)] \\ &= s_{B,c}(t) \cos(2\pi f_c t) - s_{B,s}(t) \sin(2\pi f_c t) \end{aligned}$$

where $a(t) \geq 0$ and $\theta(t)$ are the amplitude or envelope and the phase of the signal $s_B(t)$, respectively. The phase $\theta(t)$ is measured with respect to the carrier $\cos(2\pi f_c t)$. The signals $s_{B,c}(t)$ and $s_{B,s}(t)$ are the in-phase and quadrature components of the signal $s_B(t)$, respectively, also measured with respect to the carrier $\cos(2\pi f_c t)$. The complex envelope is a complex-valued signal that includes all of the information about both the amplitude and phase modulation of the bandpass signal. A complex-valued signal, an ordered pair of two real signals, is an extension of the concept of a complex number.

It is easiest to understand the complex envelope concept in the frequency domain. When defining the complex envelope, we need the Hilbert transform $\hat{s}_B(t)$ of the original signal $s_B(t)$, or

$$\hat{s}_B(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{s_B(\tau)}{t - \tau} d\tau \longleftrightarrow \hat{S}_B(f) = \begin{cases} -jS_B(f), & f > 0 \\ +jS_B(f), & f < 0 \end{cases}$$

where \longleftrightarrow refers to a Fourier transform pair; τ is the delay, $S_B(f) = \int_{-\infty}^{\infty} s_B(t) \exp(-j2\pi ft) dt$ is the Fourier transform or spectrum of $s_B(t)$, j is the imaginary unit, and \exp refers to a power of e ($e = 2.718\dots$) so that $\exp(x) = e^x$. The Hilbert transformer shifts positive frequencies by $-\pi/2$ radians (rad) and negative frequencies by $+\pi/2$ rad ($j = e^{j\pi/2}$ and $j^2 = e^{j\pi} = -1$). We also note that for real signals the Fourier transform is symmetric, or $S_B(-f) = S_B^*(f)$, where the asterisk (*) refers to a complex conjugate. The complex envelope is defined to be

$$\begin{aligned} s(t) &= [s_B(t) + j\hat{s}_B(t)] \exp(-j2\pi f_c t) \longleftrightarrow S(f) \\ &= \begin{cases} 2S_B(f + f_c), & f > -f_c \\ 0, & f < -f_c \end{cases} \end{aligned}$$

Because of the symmetry $S_B(-f) = S_B^*(f)$, no information is lost and the original bandpass signal can be computed from

$$\begin{aligned} s_B(t) &= \text{Re}[s(t) \exp(j2\pi f_c t)] \leftrightarrow \\ S_B(f) &= \frac{1}{2} S^*(-f - f_c) + \frac{1}{2} S(f - f_c) \end{aligned}$$

where Re denotes the real part. For a complex number z , $\text{Re}(z) = (1/2)(z^* + z)$. The complex envelope $s(t)$ is up-converted to the carrier frequency, and the spectrum at positive and negative frequencies divided by two appears when the real part of the signal is taken. The imaginary part includes the Hilbert transform of the original signal, or $\hat{s}_B(t) = \text{Im}[s(t) \exp(j2\pi f_c t)]$.

We next derive the complex envelope for the bandpass signal $s_B(t) = s_{B,c}(t) \cos(2\pi f_c t) - s_{B,s}(t) \sin(2\pi f_c t)$ with $W < f_c$ (Haykin 1983). We first note that $\cos(x) = (1/2)[\exp(jx) + \exp(-jx)]$, $\sin(x) = (1/2j)[\exp(jx) - \exp(-jx)]$, and $\hat{s}_B(t) = s_{B,c}(t) \sin(2\pi f_c t) + s_{B,s}(t) \cos(2\pi f_c t)$ (Haykin 1983). Therefore, we obtain by direct substitution $s(t) = [s_B(t) + j\hat{s}_B(t)] \exp(-j2\pi f_c t) = s_{B,c}(t) + js_{B,s}(t)$, a surprisingly simple result that is valid when $W < f_c$ or the spectra $S^*(-f - f_c)$ and $S(f - f_c)$ at negative and positive frequencies do not

overlap. Thus, the in-phase and quadrature components of the original signal are $s_{B,c}(t) = \text{Re}[s(t)]$ and $s_{B,s}(t) = \text{Im}[s(t)]$, respectively. In a similar way the magnitude of the complex envelope is the envelope of the original signal or $a(t) = |s(t)|$, and the phase is $\theta(t) = \arg[s(t)]$, where \arg refers to the phase of $s(t)$. Each operation made for the complex envelope has a corresponding operation for the bandpass signal. In simulations, all of the signals are time-discrete and complex, but it is convenient to express the equations in a time-continuous form.

ADDITIVE NOISE AND INTERFERENCE

We assume that the noise $z(t) = z_c(t) + jz_s(t)$ is additive and WSS (Proakis 2001), usually added at the output of the channel model to the received signal (Figure 1). Here $z_c(t)$ and $z_s(t)$ are the real and imaginary parts of $z(t)$, respectively. According to the central limit theorem, the sum of many independent zero mean complex noise sources is approximately Gaussian, or its bivariate probability density function has the form

$$\begin{aligned} p_z(z) &= p_{z_c, z_s}(z_c, z_s) = p_{z_c}(z_c) p_{z_s}(z_s) \\ &= \frac{1}{2\pi\sigma^2} \exp[-(z_c^2 + z_s^2) / 2\sigma^2] \end{aligned}$$

where σ^2 is the variance of both $z_c(t)$ and $z_s(t)$, which are assumed to be uncorrelated. Thus, the probability density function is obtained by multiplying the marginal probability density functions $p_{z_c}(z_c)$ and $p_{z_s}(z_s)$.

We usually assume that the noise has an ideal autocorrelation function $\phi_{zz}(\tau)$ or

$$\phi_{zz}(\tau) = E[z(t + \tau) z^*(t)] = N_0 \delta(\tau) \longleftrightarrow \Phi_{zz}(f) = N_0$$

where τ is the delay, E denotes statistical mean, the asterisk (*) refers to complex conjugation, N_0 is a real non-negative constant, $\delta(t)$ is the unit impulse function, and $\Phi_{zz}(f)$ is the noise power spectral density, which is uniform. The noise is called *white noise* with the power spectral density of N_0 . We have used the Wiener-Khinchine relation, according to which the autocorrelation function and the power spectral density of a random signal form a Fourier transform pair.

Complex Gaussian noise $z(t)$ is easy to analyze because such noise will remain Gaussian in a linear system. White noise is not always Gaussian. The term *white* refers only to the form of the spectrum, not to the amplitude distribution. On the other hand, Gaussian noise can also be nonwhite or colored. No physical noise source can have an infinite bandwidth, which would imply an infinite variance or power. However, it is enough that the noise is white within the signal bandwidth because the noise outside the signal bandwidth is usually filtered. Thermal noise is approximately *additive white Gaussian noise* (AWGN). According to the information theory, AWGN is the most detrimental additive noise. Therefore, AWGN is by far the most common noise model.

In digital transmission, the channel model is usually normalized in such a way that the average received energy

per bit E_b divided by the noise power spectral density N_0 obtains a reasonable value. The ratio E_b/N_0 must be above $\ln 2$ or $10\lg(\ln 2) \approx -1.6$ decibels (dB), which is the Shannon limit (\ln refers to natural logarithm of base e and \lg refers to Brigg's logarithm of base 10). Below the Shannon limit it is not possible to obtain error-free transmission even in theory. The ratio E_b/N_0 cannot be made arbitrarily large in cellular communications systems because the transmitted energy is finite and users would interfere with each other. There are also safety reasons to limit the transmitted energy. Usually the ratio is below, say, 30 dB to 40 dB (Proakis 2001).

Cellular communications systems are also subject to impulsive noise such as automotive ignition noise and atmospheric noise. However, such noise types are usually not considered important in performance studies at the large frequencies of interest. In addition, the received signal usually includes some additive *multiple access interference* (MAI), $i(t)$, from other users of the channel (Rappaport 2002) (see Figure 1). In cellular systems, the same frequencies are used again at a distance where the channel path loss is large enough. Also, the filters in the system are never ideal. Thus, the MAI can be either co-channel or adjacent channel interference. Modeling of the interference is complicated because of the many parameters involved. For example, each interference source has its own channel model.

PATH LOSS AND SHADOWING

The radio waves are distributed to all directions from the transmitter antenna. In addition, in the signal path there are obstacles where the signal is further attenuated because of absorption. The total attenuation includes a mean that we call *path loss* and slow random changes that we call *shadowing*. We neglect multipath propagation for the time being. The received signal $r(t)$ without noise and multipath fading has the form (Proakis 2001)

$$r(t) = \sqrt{\Psi} g(t) s(t)$$

where $\Psi = P_r/P_t$ represents the path loss, P_t is the average transmitted power, P_r is the average received power at a given distance d from the base station, $g(t)$ is the shadowing, and $s(t)$ is the transmitted signal represented by the complex envelope (Figure 1).

Path Loss

There are several path loss models summarized in the literature (Rappaport 2002). For our purposes, it is enough to present the simplified path loss model (Goldsmith 2005):

$$\Psi = \frac{P_r}{P_t} = K \left(\frac{d_0}{d} \right)^\gamma$$

where $K < 1$ is a unitless constant that depends on the antenna characteristics and the average channel attenuation, d_0 is a reference distance for the antenna far field

(typically 10 m to 100 m outdoors), d is the distance between the transmitter and the receiver ($d > d_0$), and γ is the path loss exponent. The constants K , d_0 , and γ are usually determined from empirical measurements.

In free space, the path loss exponent is $\gamma = 2$. In urban microcells, the path loss exponent is 2.7 to 3.5; in urban macrocells, it is 3.7 to 6.5 (Goldsmith 2005).

Shadowing

The path loss depends not only on the distance but also on the objects in the signal path. The received power at a given distance is random. If the attenuation is expressed in decibels, then it is normally or Gaussian-distributed. Thus, a typical model for shadowing is log-normal with the probability density function $p_g(g)$ in the linear scale (Coulson, Williamson, and Vaughan 1998; Goldsmith 2005)

$$p_g(g) = \frac{\xi}{\sqrt{2\pi}\sigma_s g} \exp\left[-\frac{[\xi \ln(g) - \mu_s]^2}{2\sigma_s^2}\right], g \geq 0$$

where μ_s is the path loss (dB) averaged in decibels, σ_s is the standard deviation (dB) of the path loss averaged in decibels, and $\xi = 10/\ln 10$. Typically σ_s ranges from 4 dB to 13 dB in outdoor channels (Goldsmith 2005).

The attenuation resulting from shadowing is assumed to be a product of positive, random, and independent attenuation factors coming from the obstacles between the transmitter and the receiver. The logarithm of the product of several random variables is the sum of the logarithms of the random variables, and thus we can apply the central limit theorem to the sum, which is normally distributed. The product itself is therefore log-normally distributed.

Because of the nonlinearity of the logarithm function in the definition of decibels, the actual path loss averaged in the linear scale and presented in decibels is

$$\rho_s = 10 \lg \psi = \mu_s + \frac{\sigma_s^2}{2\xi}$$

It is the common practice that the path loss is averaged in the linear scale (Rappaport 2002).

Shadowing is typically caused by large objects in the signal path. For example, when a receiver is moving, a tall building may enter between the transmitter and the receiver, increasing the attenuation of the received signal. The receiver continues to move and, after some time, the building is no longer in the signal path and the power of the received signal increases again. Shadowing is essentially frequency-nonselective fading such that it affects all frequencies of the signal in a similar manner.

MULTIPATH FADING

A linear multipath fading channel is fully described by its time-variant impulse response $h(\tau, t)$ where τ is the delay and t is the time (Bello 1963; Proakis 2001). Early important work on WSS fading multipath channel models in a more general framework came from Turin, Kailath, and

Bello in the 1950s and 1960s (Bello 1963; Kailath 1963; Turin 1980). The channel is equivalently characterized by its time-variant transfer function $H(f, t) = \int_{-\infty}^{\infty} h(\tau, t) \exp(-j2\pi f\tau) d\tau$, which is the Fourier transform of the impulse response with respect to the delay parameter (f is the frequency).

If the transmitted signal is denoted by $s(t)$, then the received signal $r(t)$, without path loss, shadowing, and interference and noise, is given by the convolution integral $r(t) = \int_{-\infty}^{\infty} s(t - \tau) h(t, \tau) d\tau$.

Alternatively, the received signal is $r(t) = \int_{-\infty}^{\infty} S(f) H(f, t) \exp(j2\pi f t) df$. We emphasize that the Fourier transform $R(f)$ of $r(t)$ is *not* $S(f) H(f, t)$ in time-variant systems: $R(f)$ is time-invariant, but $S(f) H(f, t)$ is time-variant. To compute $R(f)$, we need first to compute $r(t)$ and then find its Fourier transform. In general, the channel is frequency-selective, implying that different frequencies are affected differently. Frequency selectivity comes from the memory of the impulse response on the delay axis. If $H(f, t)$ depends only on time t and not on frequency f , the then channel is frequency-nonselective and we denote its transfer function by $H(t)$. In that case, we find that $r(t) = \int_{-\infty}^{\infty} S(f) H(t) \exp(j2\pi f t) df = H(t)s(t)$. Therefore, a special case of convolution is multiplication.

The magnitude $|H(f, t)|$ of the transfer function at a given frequency f is changing randomly in time, and we say that the mobile radio channel is a *fading* channel. The phase $\arg[H(f, t)]$ is also a random function of time. Multipath fading is caused by multipath propagation resulting from reflection, scattering, and diffraction of the radio waves from nearby objects such as buildings, vehicles, hills, and mountains.

In the following discussion, we neglect the amplitude changes of the multipath components themselves for simplicity. Multipath fading is easiest to understand when an unmodulated carrier $\cos(2\pi f t)$ at a certain frequency $f = c/\lambda$ is used as a test signal where λ is the wavelength and c is the velocity of the radio waves. When the mobile station is moved, the path length $d(t)$ of each multipath component changes randomly, and therefore the delay $\tau(t) = d(t)/c$ is changed. Thus, the received signal is a sum of attenuated carriers of the form $\cos[2\pi f [t - \tau(t)]] = \cos[2\pi f t + \varphi(t, f)]$, whose phases $\varphi(t, f) = -2\pi f \tau(t)$ are randomly changing.

There can be additional phase changes—for example, in reflections—but we neglect them for the time being. Multipath fading is a result from addition of such carriers with randomly and independently changing phases, which can cause either constructive or destructive fading when the carriers are added in the same phase or in the opposite phase, respectively.

If the delay $\tau(t)$ is changed only by $\lambda/2$, then the phase $\varphi(t, f)$ at a given frequency is changed by $-\pi$ rad. This means that the mobile station needs to be changed only a few tens of centimeters, and the fading may change from constructive to destructive or vice versa. We say that the fading channel is *time-selective*—that is, the attenuation depends on time. The phases $\varphi(t, f)$ depend on frequency for the same delay $\tau(t)$, and thus the channel is in general also frequency-selective—that is, the attenuation depends on frequency. For a given delay $\tau(t)$ at a certain time t , the phase $\varphi(t, f)$ is changed by $-\pi$ rad if the frequency

f is changed by $1/2\tau(t)$. With respect to a stationary base station, multipath propagation creates a random frequency-dependent standing wave pattern through which the mobile station moves (Stein 1987).

The changing delays also cause a Doppler effect. For simplicity, let us consider only the *line-of-sight* (LOS) component coming directly from the base station. A similar phenomenon occurs for all multipath components. The velocity of the mobile station v is assumed to be constant. The delay is linearly changing according to $\tau(t) = \tau_0 - vt \cos \alpha_v/c$, where τ_0 is the initial delay, and α_v is the angle between the half line from the mobile station toward the base station and the velocity vector. The received carrier has the form $\cos[2\pi f[t - \tau(t)]] = \cos[2\pi(f + f_m \cos \alpha_v)t + \phi_0]$, where $f_m = (v/c)f_c$ is the Doppler frequency—that is, the maximum frequency shift when $\alpha_v = 0$ and $\phi_0 = -2\pi f\tau_0$ is the initial phase. The frequency shift resulting from the Doppler effect in this case is $\Delta f = f_m \cos \alpha_v$. It is positive when the delay τ is decreasing ($|\alpha_v| < \pi/2$). It is negative when the delay is increasing.

Some modern systems use directive antennae to direct the antenna beam toward the desired transmitter or receiver and to reject the interfering signals. Another way to use multiple antennae is to place them far enough from each other so that transmitted and received signals experience independent fading channels. These antenna arrays provide *diversity* and *spatial multiplexing* gain, but antenna patterns do not have directional interpretation. Conventionally, only horizontal directions are taken into account. In such systems, the direction of arrival of the received signals as well as the azimuthal power gain of the antenna are important concepts, and the models are *two-dimensional* (2D). The two dimensions are the delay and the azimuth, whereas in *one-dimensional* (1D) models the only dimension is the delay. All of the models are dependent on time, but in this case time is not counted as a dimension. Important early work on 2D models has been done by Clarke in the 1960s (Ertel et al. 1998). However, elevation is important in single-frequency networks as in the UMTS, where intercell interference and cell coverage can be effectively controlled by tilting base station antennae mechanically or electronically (Laiho, Wacker, and Novosad 2002). In CDMA systems, all of the cells can use the same frequencies because of the immunity of CDMA receivers to interference.

The channel models are used for performance analysis and simulations of mobile systems. The models can also be used for simplified measurements in a controlled environment to guarantee repeatability and to avoid the expensive measurements in the field because only the statistical parameters of the model need to be measured. However, any model is only an approximation of the actual propagation in the field. For measurements, the average received *signal-to-noise ratio* (SNR) must be defined. It is estimated by making a link power budget (Proakis 2001) that includes the transmitter power, distance-dependent attenuation of the channel, antenna gains in the transmitter and receiver, and various loss factors and margins. It depends on the system designer whether a margin for fading is taken into account or whether the performance simulations or measurements with the channel model will include fading. The power of additive noise is also estimated for modeling purposes.

One-Dimensional Models

The multipath fading model is either one-dimensional or two-dimensional. We will first consider 1D models, which are described by the time-variant impulse response and transfer function (Bello 1963; Proakis 2001). If the transmitted signal has a bandwidth of W , then the delay resolution of the measurement is approximately $1/W$, which means that the receiver cannot resolve delay differences smaller than $1/W$. We define such unresolved multipath components as clusters on the delay axis (Turin 1980). The receiver can resolve multipath components whose delay differences are larger than $1/W$. We will apply the central limit theorem for the clusters.

The impulse response has the general form $h(\tau, t) = \sum_{l=0}^{L-1} h_l(t) \delta(\tau - \tau_l)$, where L is the number of resolvable clusters whose complex amplitudes are $h_l(t)$ and delays are τ_l . Because the channel is random, we need a stochastic description for it. The delays of the clusters are usually assumed to be constant in channel models because they are changing slowly compared to the time interval $1/W$, but it must be noted that fading is mainly caused by the randomly changing delays, which change the relative phase shift between the multipath components within the clusters.

If several multipath signals caused by scattering with approximately equal amplitudes, or alternatively with random amplitudes, are added at random phases, then the resultant has a complex Gaussian distribution with a zero mean. The amplitude of such a cluster is Rayleigh distributed and the phase is uniformly distributed. The channel is then said to be a *Rayleigh fading channel*. Alternatively, if in addition to the scattered components, the received signal includes a strong component, which is either an LOS signal coming directly from the transmitter or from a specular reflection, the impulse response at that delay will have a Gaussian distribution with a nonzero mean, and the amplitude is Ricean distributed. In this case, the channel is a *Ricean fading channel*. In both Rayleigh and Ricean fading channels, only the first- and second-order statistics, including the mean and autocorrelation functions, are needed to fully describe them. A more general description is the covariance matrix of a discretized impulse response.

For multipath fading, a widely used model is a *wide sense stationary uncorrelated scattering* (WSSUS) model (Bello 1963). It is WSS with respect to the time variable. *Uncorrelated scattering* means that the autocorrelation function of the WSS Rayleigh fading impulse response has the form $E[h^*(\tau, t) h(\tau + \Delta\tau, t + \Delta t)] = P_h(\tau, \Delta t) \delta(\Delta\tau)$, or there is no correlation on the τ axis but some correlation may exist on the time axis. The function $P_h(\tau, \Delta t)$ is the autocorrelation of the impulse response at the delay τ with the time difference Δt . With the time difference $\Delta t = 0$, we obtain the average power density $P_h(\tau, 0) = P_h(\tau) = E[|h(\tau, t)|^2]$ of the impulse response at the delay τ , and the average is taken over time t . Therefore, the function $P_h(\tau)$ is called the *delay power spectrum* of the channel. The impulse response is nonstationary white noise in the delay variable. It can be shown that in a WSSUS channel the transfer function is WSS also with respect to the frequency variable (Bello 1963).

The Fourier transform of $P_h(\tau, \Delta t)$ with respect of the time difference Δt is the *scattering function* $S(\tau, \Delta f)$ of the channel (Bello 1963; Proakis 2001), or $S(\tau, \Delta f) = \int_{-\infty}^{\infty} P_h(\tau, \Delta t) \exp(-j2\pi\Delta f \Delta t) d\Delta t$, where Δf is the frequency shift. For a given delay τ , the scattering function as a function of Δf is the power spectral density of the impulse response. The function $S(\tau, \Delta f)$ is thus a measure of the average power density as a function of the time delay τ and the frequency shift Δf . The delay power spectrum is $P_h(\tau) = \int_{-\infty}^{\infty} S(\tau, \Delta f) d\Delta f$. If we transmit several times a narrow pulse through the multipath channel with a large enough spacing so that the received responses are not overlapping and then average the received power density on the delay axis, the result has approximately the form of the delay power spectrum. The *Doppler power spectrum* is $S_H(\Delta f) = \int_{-\infty}^{\infty} S(\tau, \Delta f) d\tau$. If we transmit an unmodulated carrier through the fading channel, the carrier is modulated by the channel, and the received power spectral density has approximately the form of the Doppler power spectrum.

The width of the delay power spectrum is referred to as the *multipath spread*, and the width of the Doppler power spectrum is referred to as the *Doppler spread*. A suitable engineering definition is used for the width. The channel is frequency-nonselective or flat fading if the signal bandwidth W is much smaller than the inverse of the multipath spread, or the coherence bandwidth; otherwise the channel is frequency-selective. The Doppler spread and its inverse, or the coherence time, are measures of the rapidity of fading.

A typical approximation for the delay power spectrum is exponential with respect to the delay variable τ . A typical approximation for the Doppler power spectrum is $S_H(\Delta f) = (1/\pi f_m)[1 - (\Delta f/f_m)^2]^{-1/2}$, where $f_m = (v/c)f_c$ is the Doppler frequency, v is the velocity of the mobile station, and f_c is the carrier frequency. This Doppler power spectrum is based on the assumption that the multipath components arrive at the omnidirectional antenna uniformly from all horizontal directions. It is often referred to as *Jakes's Doppler power spectrum* (Jakes 1974) even though it was derived earlier by Clarke (Rappaport 2002). This is a reasonable approximation in cellular communications systems where scatterers are located close to mobile stations.

At any time instant, the multipath components arrive from distinct directions, but when the mobile station is moving in the scattering environment and the received directions are averaged over time, the average received direction becomes uniformly distributed. Conversely, scatterers are located far away from high-elevated base station antennae, especially in macrocells, and the azimuthal power spectrum of the received signal can be parameterized by Laplacian distribution (Pedersen, Mogensen, and Fleury 2000). In *wireless local area networks* (WLANs), transmitters and receivers are stationary and Doppler power spectrum is caused by moving objects, such as people and vehicles, in the propagation environment. Thus, characteristics of Doppler power spectrum in WLANs are different from those in cellular systems.

In addition to Rayleigh and Ricean distributions, a useful amplitude distribution for the multipath fading is a *Nakagami- m distribution* (Proakis 2001), which is, in fact, a form of the generalized Rayleigh distribution.

When selecting a suitable distribution, one should note that for system performance, the most notable effect has the distribution at small amplitudes (Stein 1987).

Two-Dimensional Models

Fourth-generation research targets to wide bandwidths and peak throughputs as high as 1 Gbit/s. Although bandwidths as high as 100 MHz are envisioned, the proposed data rate target is especially challenging because it assumes spectral efficiency as high as 10 bit/s/Hz; current cellular systems achieve the spectral efficiency of 0.05 bit/s/Hz to 2 bit/s/Hz. Multiantenna transceivers are generally considered as one of the most efficient options to increase the spectral efficiency, and 2D and even 3D channel models are needed to develop and analyze such transceivers.

The most attractive feature of *multiple-input multiple-output* (MIMO) channels using many antennae in the transmitter or receiver is that the capacity of these channels increases linearly as a function of the number of transmitter or receiver antennae. If the numbers of antennae in the transmitter and receiver are different, then we use the smaller of the two numbers. The increase of the capacity in MIMO systems is remarkable because the capacity of *single-input single-output* (SISO) channels increases only logarithmically as a function of SNR (Proakis 2001). This seriously limits the spectral efficiency of SISO systems in cellular communications channels because large transmitter powers create large interference in cellular systems.

The high spectral efficiency of MIMO systems results from their capability of spatial multiplexing in the case of rich scattering environment. This is illustrated in Figure 2 by using the angular domain decomposition (Sayeed 2002) of MIMO channels and the clustering phenomenon (Saleh and Valenzuela 1987) of multipath components. Channel measurements have shown that multipath components tend to arrive in clusters, with each cluster of signal paths resulting from a group of scattering objects in the propagation environment. Such a group can consist of, for example, nearby walls in an office.

The resolution of the antenna arrays in the angular domain determines how many signal paths can be separated in the receiver. This is analogous to the resolvability of band-limited signals in the time domain where the receiver is not able to resolve delay differences shorter than $1/W$. In the same vein, an antenna array of length L is not able to separate signals whose directional cosines with respect to the antenna array differ less than $1/L$. This is illustrated in Figure 2 where the receiver antenna array has four different angular sectors numbered from 1 to 4. All sectors of the receiver antenna array are excited by signal components resulting from different clusters of scatterers. In contrast, if there were only one cluster of scatterers, then all signal paths would arrive in the same sector. Signals that arrive from the same angular sector cannot be separated in the receiver; in Figure 2, these signal components are scattered from the same cluster of scatterers. Thus, the performance of the MIMO system depends intimately on the structure of the scattering environment and the resolution of the antenna arrays.

Examples for possible structures of MIMO channels are depicted in the bottom part of Figure 2, where the

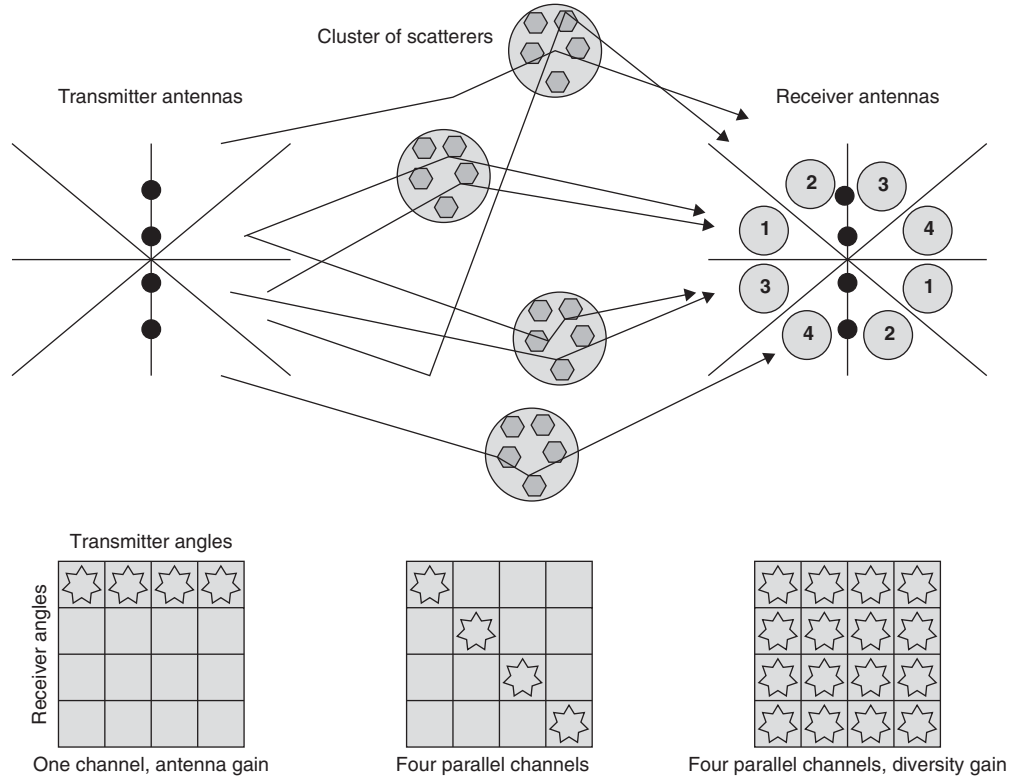

Figure 2: Schematic representation of a MIMO channel in angular domain and examples of coupling between transmitter and receiver angles

stars indicate that corresponding received and angular sectors are connected by a cluster of scatterers. In the leftmost case, the transmission is received by one angular sector; and the received signal has a clear direction. Spatial multiplexing is not possible, and the capacity increases logarithmically, but the system obtains an SNR gain. In the central box, one transmitter sector is connected to exactly one receiver sector. Now a MIMO system can set up four parallel channels that do not interfere with each other. Medium access control could then acknowledge that the transceiver is able to support four parallel links. However, this case is highly improbable in wireless channels unless the transmitter knows the forward channel, which enables it to form four orthogonal transmitter beams. The rightmost case corresponds to a situation in which all angular transmitter sectors contribute to all receiver sectors. This is the case in rich scattering environment where the capacity of MIMO system increases linearly as a function of the number of transceiver antennae even when the transmitter has no information on the forward channel (Telatar 1999). A lot of research have been devoted to modeling the structure of the 2D scattering environment and its effect on the performance of MIMO systems.

The 1D WSSUS model can be generalized to the 2D case as follows. The azimuth or the angle of arrival relative to the velocity vector of the mobile station is denoted by α . As previously, the multipath components are combined into clusters in space with a delay resolution of $1/W$ and with an angular resolution $\Delta\alpha$ of the receiver antenna. Each

cluster has a Rayleigh or Ricean fading amplitude. Each complex gain of the impulse response has now the general form $h_l(t) = \sum_{n=0}^{N-1} a_{ln} \exp[j(\varphi_{ln} + 2\pi f_m t \cos(\alpha_{ln}))]$, where α_{ln} is the azimuth of arrival, φ_{ln} is the phase of the n th component in the l th delay, and N is the number of components in the model at the l th delay. As a generalization of the delay power spectrum, we can define an *azimuthal delay power spectrum* that shows the distribution of the received power versus azimuth and delay.

For a given velocity and direction of the mobile station, and for a given azimuthal power gain of the antenna, the azimuthal delay power spectrum corresponds to a certain scattering function of the WSSUS channel (see Figure 3).

The scattering function is an aliased form of the azimuthal delay power spectrum because two different azimuths α_{ln} and $-\alpha_{ln}$ of arriving clusters create the same frequency shift because of the cosine function in $h_l(t)$. Given a uniform distribution $p_a(\alpha)$ for the received power in mobile station, we obtain Clarke's Doppler power spectrum given earlier; because of the reciprocity of the channel, the Doppler power spectrum is the same in the base station as well. However, azimuthal power spectra in the base station and the mobile station are in general different because the signal received by the high elevated base station antennae has a clear mean direction of arrival. Azimuthal spectrum does not affect the Doppler power spectrum in the base station because the Doppler power spectrum is generated by scatterers around the mobile station. Angular domain decomposition as sketched in Figure 2 further

Figure 3: Azimuthal delay power spectrum and scattering function of the channel

increases the detail level in 2D models aiming to resolve the channel as $h_r(t, \alpha, \beta)$, where β refers to the azimuth of departure—that is, each receiver angle is mapped to the corresponding transmitter angle.

MEASUREMENT OF LINEAR TIME-VARIANT CHANNELS

Channel measurements can be divided into narrowband and wideband measurements. Wideband measurements use measurement signals, which have about the same bandwidth as the intended information signal. Unlike narrowband measurements, which use a single unmodulated carrier as a measurement signal, wideband measurements provide information on the multipath propagation as well as frequency selectivity of the channel. Therefore, only wideband measurements are discussed here. The measurements can also be divided into measurement of (1) instantaneous values of the impulse response and (2) the average parameters of the channel. The average parameters include first- and second-order statistics, or the mean and the autocorrelation function of the impulse response, and the scattering function of the channel. Several ways to perform systematic measurements have been listed in Hewitt and Vilar (1988) and Pahlavan and Levesque (1995).

The problem of the measurement of system functions of time-variant channels differs from that of the time-invariant case. Even in the absence of noise, the system function of a time-variant channel may be unmeasurable. The condition on the measurability of a linear time-varying WSSUS channel was first presented by Kailath (1963) and later extended in Bello (1969). It turns out that the channel measurability depends on the value of the area spread factor, which is the area of region where the scattering function is effectively nonzero. If the area spread factor is less than or equal to a threshold, then the channel impulse response could be measured unambiguously (Bello 1969). The value of the threshold is on the order of unity. The channels for which the area spread factor fulfills the criterion mentioned above are called *underspread*; otherwise, they are called *overspread*. If the channel is overspread, then it is not possible to measure the instantaneous values of the impulse response, even in the absence of the noise.

Fortunately, most physical channels are underspread. The average parameters can be determined either from the instantaneous values of the channel impulse response or by cross-correlation methods. Because the statistical averages contain much less information than the instantaneous values, the channel need not always be underspread before the average parameters could be measured.

Two practical methods to measure the impulse response of the underspread cellular channel can be identified (Hewitt and Vilar 1988). One method is to transmit an extremely short impulse-like pulse to the channel and observe the multiple pulses received. To follow the time variation of the channel, the pulses need to be transmitted periodically. The short pulses result in a high ratio of peak to average transmission power, which could be undesirable. Another, more efficient method to measure the impulse response is the use of direct sequence spread-spectrum signals (Pahlavan and Levesque 1995). A pseudonoise sequence is used to modulate the carrier. *Maximal length sequences* (m sequences) are widely used because of their excellent periodic autocorrelation properties.

The receiver is based on a correlation principle. It can be implemented by a matched filter or a sliding correlator (Hewitt and Vilar 1988). Nowadays, high-speed digital signal-processing techniques can be employed to implement real-time matched filter channel sounders. In a WSSUS channel, time averaging can be used to obtain the autocorrelation function of the measured impulse response. An estimate of the scattering function can then be computed by the Fourier transform (Braun and Dersch 1991; Dersch and Zollinger 1994). Angle of arrival measurements can be conducted by using directional or array antennae at the receiver (Ertel et al. 1998). To some extent, angle of arrival can be deduced from the estimated scattering function (Braun and Dersch 1991). The number of samples in the spatial domain is strictly limited by the number of receiver antennae, and therefore high-resolution estimation techniques such as *multiple signal classification* and *space-alternating generalized expectation maximization* are often applied to estimate azimuthal directions.

One of the earliest measurement results of the impulse response of the cellular channel in urban and suburban areas by using short pulses were reported by Turin et al. in 1972 (Turin 1980). The delay, amplitude, and phase of multipath components were measured at three different

frequencies simultaneously. It was found that spatial correlation distances of these variables at neighboring geographical points varied considerably. They ranged from less than a wavelength for the phases, through tens of wavelengths for the amplitudes and delays, to hundreds of wavelengths for the means and variances, or powers, of the amplitudes.

More recent measurement studies have used almost exclusively the direct sequence spread-spectrum signals with m-sequences to measure the channel. Wideband macrocell measurements conducted at 1 GHz show that in typical urban areas the multipath spread from 1 μ s to 2 μ s is characteristic. In suburban areas, multipath spreads from 10 μ s to 20 μ s are typical. The longest multipath spreads occur in mountainous environments where multipath spreads from 100 μ s to 150 μ s have been encountered. In open areas, the multipath spread is practically nonexistent and the received signal consists of the directly propagated LOS component only (Braun and Dersch 1991). Wideband measurements in urban microcell environments at 2 GHz have been reported in Dersch and Zollinger (1994). The delay power spectrum, average normalized correlation functions, and scattering functions have been computed from the measured impulse response. Under LOS conditions, the direct component with unresolvable specular reflections dominated the propagation. Some resolvable specular reflections existed at multipath spreads of as much as 1.5 μ s.

In non-LOS situations, the powers of the strongest received signals were more than 15 dB below the LOS components that resulted in nearby locations. The propagation process was found to be dominated by multiple reflections and scattering along the streets, not by diffraction (Dersch and Zollinger 1994).

Several results on spatial channel measurements have been published in recent years. Some results have been summarized in Ertel et al. (1998). Measurements conducted at 2 GHz with a 10 MHz bandwidth, by using a rotating azimuth beam directional antenna at the receiver, have shown that delay and angle of arrival spreads are small in rural, suburban, and even many urban environments. Measurements in urban areas have shown that most of the major features of the delay and angle of arrival spectra can be accounted for by considering the large buildings in the environment. Finally, the variation in the spatial characteristics with both time and frequency have been measured. The results indicate that the uplink spatial characteristics cannot be directly applied for downlink beam forming in most current cellular and personal communication systems that have 45 MHz and 80 MHz of separation between the uplink and downlink frequencies, respectively (Ertel et al. 1998).

True spatio-temporal measurements of the time-varying channel would require multichannel sounders, which are complex and expensive. To this end, simpler measurement techniques have been developed in which the location of a single receiver antenna is altered with a predetermined pattern or a receiver is connected to one element of an antenna array at a time using a fast switch at the radio frequency (Kalliola et al. 2003). Finding the coupling between transmitter and receiver angles requires a large number of parameters to be estimated and

fitting measurements to a deterministic model becomes cumbersome when the number of antennae in the model is increasing. The number of estimated parameters can be reduced by using stochastic channel models.

SIMULATION MODELS

Simulation models are divided into link and system level models. Both of them are considered in this section.

Link-Level Simulation Models

The evolution of channel simulation models has been parallel to that of cellular systems. The early models considered only the signal amplitude level distributions and Doppler spreads of the received signals. Frequency selectivity was later added to the channel models. In addition to those, modern channel models include also such concepts as angle of arrival and adaptive array antenna geometries. The signal parameters that need to be simulated in these models for each multipath component are the amplitude, carrier phase shift, time delay, angle of arrival, and frequency shift. In general, all of these parameters are time varying, causing Doppler spread in addition to multipath spread (Ertel et al. 1998).

The channel simulators can be categorized into three classes according to the way the channel impulse response is modeled: stored channel impulse response, ray tracing models, and stochastic parametric models for the channel impulse response. The stored channel impulse responses are based on selected measurements, which are then stored for later use. Although this method provides actual information from the channel, the proper selection criteria for the measurements may be difficult to identify. Also, the large amount of data needed to store the measurement results could be difficult to handle. However, some models have been proposed in Ertel et al. (1998) and Fleury and Leuthold (1996). The ray tracing models are deterministic. They are based on geometric propagation theory and reflection, diffraction, and scattering models. Accurate channel models are possible using this method. However, the high computational burden and lack of detailed terrain and building databases make these models difficult to use (Ertel et al. 1998).

By far the most popular channel simulation models are stochastic parametric models. In this approach, the channel impulse response is characterized by a set of deterministic and random parameters. The values of the parameters and the probability distributions governing their behavior are selected according to measurements. Such models are easy to use and fast when compared to ray tracing. The remaining challenge is to develop models that exhaustively reproduce the propagation scenarios accounted in reality (Fleury and Leuthold 1996). A recommended summary of stochastic channel models can be found in Fleury and Leuthold (1996). Spatial or 2D stochastic channel models are summarized in Ertel et al. (1998) and Yu and Ottersten (2002).

Usually, discrete-time channel impulse responses in the form of transversal filters are used in the stochastic channel simulators. The transversal filter model allows the simulators to be implemented either by software

or hardware. The time-varying complex coefficients and delays of the transversal filter are generated according to the statistics associated with the different parameters. In 2D models, the filter taps are matrices instead of scalars as in 1D models. The matrices capture the spatial structure of each delay tap. The amplitudes are usually assumed to be Rayleigh or Ricean distributed because of multipath fading. A uniform and Poisson distribution is usually assumed for the phases and delays, respectively. However, in a Ricean fading channel, the phase is concentrated around the phase of the strong component unless there is a frequency shift in it.

As mentioned earlier, the delay power spectrum is typically approximated by an exponential function. There are several methods to simulate the angles of arrival. For example, in Olmos et al. (1999), they are modeled as normally distributed random variables. Other methods have been summarized in Ertel et al. (1998). Rayleigh and Ricean processes needed to simulate the amplitudes can be generated by using filtered complex Gaussian noise processes. Typically, the Doppler power spectrum by Clarke is used, but its limitations mentioned earlier should be noted. Several alternative Doppler power spectra are listed in Simon and Alouini (2005), including rectangular, Gaussian, and first- and second-order Butterworth spectra.

A well-known method to produce colored Gaussian noise processes is to filter WGN with a filter having a transfer function of the square root of the Doppler power spectrum. Another method is based on Rice's sum of sinusoids. In this case, a colored Gaussian noise process is approximated by a finite sum of weighted and properly designed sinusoids (Pätzold 2002). The long-term variations in the channel impulse response can be modeled by making the delays drift with time and by using an attenuation filter to model the log-normal fading caused by shadowing or transitions between different environments (Fleury and Leuthold 1996).

An exponential function is used to approximate the autocorrelation function of the shadowing as a function of distance (Gudmundson 1991), corresponding to the first-order Butterworth filter in a simulation model (Simon and Alouini 2005). A correlation distance on the order of 10 m is typically used for microcells. For macrocells, much larger correlation distances on the order of 100 m should be used. This implies that shadowing tends to be faster in microcells than in macrocells at the same terminal velocity. Because the wavelength is at most a few tens of centimeters, this also implies that shadowing is much slower than multipath fading for which the correlation distance is usually less than the wavelength. A model useful for multiple cells is presented in Viterbi (1995). In a hardware implementation, digitally controllable attenuators can be used to simulate the attenuation caused by the shadowing (Olmos et al. 1999).

Different standardization organizations are actively defining channel models as a part of the specifications of new mobile cellular systems. Their motivation is to specify the operational environment of the system and provide test parameters for manufacturers. The channel models for the second-generation digital advanced mobile phone system and the GSM mobile cellular systems were specified by the Telecommunications Industry Association in the

United States and by the European Telecommunications Standards Institute in Europe. For the third-generation cellular systems, a global standard has been defined as the International Mobile Telecommunications 2000 (IMT2000) proposal by the International Telecommunication Union. For a more thorough discussion, see Pahlavan and Levesque (1995). Lately, the standardization work of the third-generation systems has been shifted to the international 3rd Generation Partnership Project (3GPP) and 3GPP2 in the United States.

The channel models have also been developed by different research consortia in international research programs. In Europe, the Cooperation in the Field of Scientific and Technical Research (COST) projects have been extremely influential when the GSM and digital communication system at 1800 MHz (DCS 1800) systems were developed. The achievements in the COST 259 project partly stimulated the UMTS Code-Division Testbed (CODIT) project within the Research and Development in Advanced Communication Technologies in Europe II (RACE II) program. The CODIT 2D channel models are directional models with multiple antennae in the base station and a single antenna in the mobile station. Recent channel models developed in COST 273 and in the Intelligent MultiElement Transmit and Receive Antennae (I-METRA) and Wireless World Initiative New Radio (WINNER) projects, funded also by the European Union, concentrate on MIMO models. Two-dimensional channel models have also been developed within IEEE 802.11n and IEEE 802.16e standardization.

System-Level Simulation Models

Link-level simulations are not enough to assess the performance of cellular communication system, but system-level simulations are required. Detailed modeling of cellular communications systems is still too demanding computationally, which gives rise to simplified approaches. According to the two-stage approach described in Holma and Toskala (2002), link-level simulations in the resolution defined by the signal bandwidth are first performed to obtain required quality-of-service (QoS) values for different services and mobile classes. This information is further compressed to radio frame resolution and used as an input for a system simulator. The resolution in time drops from 1/3.84 MHz in link-level simulations to 1/1.5 kHz in system-level simulations.

Multidimensional MIMO channels cannot be described with a single QoS value, and large downsampling ratios in the time domain would lose important information on MIMO links. The *spatial channel model* (SCM) introduced in the 3GPP forum (3GPP 2003) divides into link-level and system-level models in which the link-level model is used for calibration purposes. The computational burden in the system-level simulation is reduced by adopting a quasi-static approach. The network is simulated in snapshots (or *drops* in 3GPP parlance), and the performance metrics are averaged over several drops. Large-scale characteristics such as the positions of mobile stations are randomly generated at the beginning of each drop, and they remain fixed within the drop. Small-scale characteristics such as wireless channel and MAI for each

mobile station are evolving during a drop. A software implementation of SCM and its extension have been described in Baum, Hansen, and Salo (2005).

CONCLUSION

Channel modeling for cellular communications is a rapidly changing area, and the models are becoming more and more accurate. Some of the recent trends are summarized here. Higher frequencies as high as approximately 60 GHz will be used in the future. The cell size is made smaller because the channel attenuation is larger at higher frequencies. Frequencies above approximately 10 GHz are also affected more by air molecules and rain. Consequently, the highest frequencies can only be used in indoor environments. Also, with the increasing data rates, the bandwidths are becoming larger, approaching 10 MHz to 100 MHz. 3D channel models are important in macrocells—for example, in urban and mountainous areas where the base station antenna is much higher than the mobile station antenna. The 3D models take into account the elevation angle of the arriving waves in addition to the azimuthal angle and the delay.

Various nonstationary models are often used. In addition to the log-normal distribution, shadowing effects are modeled with birth-death processes in which some delays suddenly appear and disappear, simulating rapid changes as in street corners and in tunnels (Chong et al. 2005). In some models, the delays are time-variant to test the delay tracking ability of the receiver. Furthermore, the models are becoming more comprehensive in the sense that they will have multiple inputs and outputs. In this way, the models can be used to simulate diversity systems with many users. Even handoffs between base stations should be simulated. Correlation and cross talk between the multiple channels are important effects in such systems. An example of cross talk is the co-channel and adjacent channel interference between the various users of the same frequency band in the same geographical region.

ACKNOWLEDGMENT

This work was partially supported by the Advanced Wireless Communication Systems project of the Academy of Finland.

GLOSSARY

- Azimuthal Delay Power Spectrum:** The average power density at the output of a fading channel as a function of the azimuth and delay.
- Complex Envelope:** A low-pass equivalent of a real bandpass signal or system.
- Delay Power Spectrum:** The average power density at the output of a fading channel as a function of the delay.
- Diversity:** Use of multiple channels to combat fading using different antennae, times, frequencies, or polarizations.
- Doppler Power Spectrum:** The power density at the output of a fading channel as a function of the frequency shift.

- Doppler Spread:** The range of values of the frequency shift over which the Doppler power spectrum is essentially nonzero.
- Fading:** Random changes in the received signal amplitude because of, for example, multipath propagation or shadowing.
- Macrocell:** In cellular systems, macrocells provide large area coverage in, for example, rural areas.
- Microcell:** Microcells cover smaller areas than macrocells, and they are typically used in areas with high user population densities and traffic volumes.
- Multipath Propagation:** Multiple transmission paths because of the reflection, scattering, and diffraction of radio waves.
- Multipath Spread:** The range of values of the delay over which the delay power spectrum is essentially nonzero.
- Multiple-Input Multiple-Output (MIMO) System:** A system model in which several antennae are used in the transmitter or receiver to obtain beam forming, diversity, or spatial multiplexing.
- Scattering Function:** The average power density at the output of a fading channel as a function of the delay and frequency shift.
- Shadowing:** Random fading because of blockage from objects in the signal path.
- Spatial Multiplexing:** Multiplexing that is based on the use of several antennae in the transmitter and receiver.
- Wide Sense Stationary (WSS) Process:** A process whose mean and autocorrelation function are time-invariant.

INTRODUCTION

Mobile communications has been around since the beginning of the twentieth century (Black 1998, Rappaport 2001, Schwartz 2005) with experimental service attempted by the maritime industry as early as 1919. Ships were pioneers in using wireless communication because their big size allowed them to carry the big antennas and heavy equipment that were then required. Commercial amplitude modulation (AM) service immediately followed in the 1920s. However, the development of portable mobile cellular devices, the next important step toward enabling individuals to communicate from almost anywhere, took another fifty years. In 1971, Bell Labs introduced the first cellular system. However, it was not commercially deployed until 1983, two years after a Nordic European consortium introduced a similar system Nordic mobile telephone (NMT). Both systems had the main advantages that made cellular communication possible: frequency reuse and handoff (or handover) between multiple base stations (BSs) that had limited coverage areas. Advanced mobile phone service (AMPS) was among the first generation of cellular systems that were introduced throughout the developed world in the early eighties. The mobile industry was then about to take off, amid the many issues that challenged the global proliferation of mobile phones. However, despite immediate demand for the first-generation systems, the industry faced limited capacity, initial high cost, and high power consumption by mobile stations (MSs). It was only after the introduction of the three main second-generation (2G) digital cellular systems (IS-95 cdmaOne, GSM, and IS-54/IS-136, which will

be explained shortly in the next section) that the mobile industry took off and never looked back. The boom of data service in the late nineties along with the emergence of the Internet as the dominant information technology application driver has motivated the telecommunication industry to follow suit and work toward convergence of mobile and wireless networks in a *data-centric* environment and become a reliable provider of multimedia service. An intermediate step in that direction was the *data-friendly* third generation (3G), which came in different flavors (UMTS and cdma2000 being the main ones). The commercialization of 3G systems is, however, taking longer than expected, as the third-generation cellular was competitively weak compared to many wireless access alternatives such as wireless local area networks (WLANs) and wireless digital subscriber line (DSL). Furthermore, implementation of 3G technologies was sluggish and was not helped by the particular global economic and geopolitical situation in the last five years. It is hoped that the fourth generation or an intermediate 3.5 generation might have a better chance to become more economically viable. In the meantime, some 3.5G standards with higher data capabilities (e.g., high-speed downlink packet access, or HSDSPA) are already introduced as a companion technology or an upgrade to 3G in many countries. The recent advent of the mobile worldwide interoperability for microwave access (WiMax) standard (also known as IEEE602.16e) as a potential competitor to the cellular technologies is also not to be overlooked. Actually, this technology has a potential to be the immediate solution for seamless first-mile wireless high-speed access (WiMax 2006a, 2006b).

With all these quickly changing standards, and despite the constant evolution of services and network architectures and protocols, the general perspective and the overall picture of cellular system design did not change much. Many features of cellular systems are getting more and more complicated, though. The air interface with its traffic and control channels now needs a media access control (MAC) layer similar to what is used in computer networks. There is also a need for more advanced mobility, location, and resource management. More advanced power control is also required.

The reader will find in the following section a more technical overview of how the cellular industry has evolved from a voice-only service (analog AMPS) to the current UMTS system, with a look ahead to future generations. In the following sections, more technical detail is given on the architecture, services, and interfaces of a second-generation (2G) cellular system. Then, principles of cellular system design, including cell planning and transceiver design, are discussed (including some expected 3G and 4G improvements). Second-generation GSM and IS-95 systems are used as the main platforms to illustrate concepts, and any differences that arise with other systems are specified when they are encountered.

OVERVIEW OF CELLULAR TELEPHONY STANDARDS

Introduction

This section introduces the key highlights of the technical standards of the first three generations of cellular systems. The main key features of these systems are shown in Table 1 (Rappaport 2001, Holma and Toskala 2001).

Intermediate generations such as general packet radio service (GPRS) and enhanced data rates for GSM evolution (EDGE) have not been included in this table due to space constraints. However, major aspects of these technologies are discussed briefly in the section entitled “Data Service in 2.5 Generation.”

The reader can refer to the glossary of abbreviations and terms at the end of the chapter for a brief explanation of some of the terms used in the table. Some subjects and related technical terms that are central to cellular system design are treated in detail in the following sections. Readers who are less familiar with communication system design concepts may want to consult the sections entitled “Principles of Cellular System Design” and “Physical Layer Transceiver Technologies” for some of the technical background details.

Table 1: Survey of Technology Features for the Cellular Standards Currently in Use

	AMPS	GSM	IS-136	IS-95	UMTS (FDD)
Year of introduction	1983	1990	1991–1993	1993	1999
Frequency bands	824–894 MHz	890–960 MHz, 1.8 GHz, and PCS band: 1.9–2 GHz	824–894 MHz and PCS band 1.9–2.0 GHz	824–894 MHz and PCS band in 1.9–2.0 GHz	1.9–2.170 GHz
Spreading factor	NA	1	1	64	Variable up to 512
Multiple access/duplexing	FDMA/FDD	TDMA/FDD	FDMA/TDMA FDD	CDMA FDD	CDMA FDD/TDD (China)
Modulation	FSK	GMSK, BT = 0.3	?/4DQPSK	QPSK/BPSK	Dual Channel QPSK
Carrier separation	30 kHz	200 kHz	30 kHz	1.25 MHz	5 MHz
Voice channels/carrier frequency	1	8	3	Theoretical maximum: 63	Theoretical maximum: 255 in Reverse link.
Channel data rate	NA	270.833 kbps	48.6 kbps	1.228 Mcps	3.84 Mcps
Power control frequency	Low	Around 2 Hz		800 Hz	1500 Hz
Diversity exploitation	None	Frequency diversity (slow hopping)	None	Rake receiver “path diversity”	Path diversity (rake) and transmit diversity
Vocoder type and rate	NA	RPE-LPT at 13 kbps	VSELP at 7.95 kbps	CELP at 13 kbps also Enhanced VRC at 8 kbps	RPE-LPT at 13 kbps
Data service	NA	9.6 kbps	9.6 kbps	9.6 kbps	144 kbps–384 kbps (2 Mbps goal)

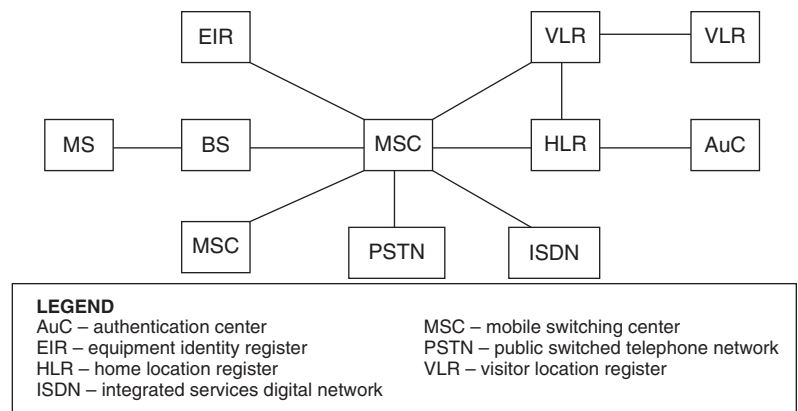

Figure 1: ANSI-41 architecture

First-Generation Cellular Systems: AMPS

First-generation systems did not consist of AMPS only. European systems also had their own versions of analog systems using frequency division multiple access (FDMA) and analog frequency modulation (FM), the first of which, as was mentioned earlier, was the NMT system. First-generation systems were incompatible and it was impossible to roam (get service across networks) between systems in different countries, especially within Europe. The need for a “global” second-generation technology was the motivation behind the introduction of a backward-incompatible GSM and the main reason why the first generation systems died out quickly in Europe whereas AMPS survived for more than two decades in geographically isolated and backward-compatibility-conscious North America, where 50 percent of mobile sales were still analog in the year 2000. It is for this reason that the discussion of first-generation systems is limited to the AMPS system here. A quick account of frequency allocations for AMPS is given in the following section, followed by an overview of the main aspects of call processing including registration, roaming, and handoff, along with an introduction to initial network architecture and signaling standards.

AMPS Architecture

AMPS was designed to support voice communication and thus all of its architecture is geared towards this service. The main elements of this architecture are the mobile station (MS), which has all the functions needed to support voice calls as a subscriber unit; the base stations (BSs),

also known as the base transceiver system (BTS), which provide the air interface to the MSs and relay signals to the rest of the network; and the mobile switching center (MSC), which provides the networking functions needed to connect the calls to other networks. A customized signaling standard called ANSI-41 is used by AMPS and all generations of North American cellular carriers. Figure 1 shows the reference model for the ANSI-41 architecture. The reader is referred to the glossary at the end for further explanation of some of the terms. The other units shown in this figure are databases that will be revisited in more detail in our discussion of second-generation systems.

AMPS Physical Layer Aspects

Table 2 lists the frequency allocations of AMPS. BS transmitter and receiver channels are separated by 45 MHz. Two cellular service providers are authorized and allocated a total of 416 channels in bands A and B, respectively. These channels can be used for voice traffic as forward or reverse voice channels (FVC and RVC, respectively), or they can be reserved as control channels (to be discussed briefly in the section entitled “AMPS Control Channels”). More detail can be found in Black (1998).

Note that frequency bands A', B', and A'' are expansions of the original systems to provide more capacity. Normally, 312 of the channels (Channels: 1–312 for System A and 354–666 for System B) are used for voice traffic. The other 21 channels in each original unexpanded system are used for control traffic, and each network is free to choose which channels to use as control channels. Generally each control channel is assigned to a given set of voice channels.

Table 2: AMPS Channels

Frequency Band	Channel Number	Reverse Link Freq. (MHz)	Forward Link Freq. (MHz)
A''	991–1023	824.04–825	869.04–870
A	1–333	825.03–834.99	870.03–879.99
B	334–666	835.02–844.98	880.02–889.98
A'	667–717	845.01–846.48	890.01–891.48
B'	718–799	846.51–848.97	889.51–883.97

AMPS Identification and Information Parameters

The following three parameters are used for subscriber and mobile identification in AMPS:

1. An electronic serial number (ESN) is required by the Federal Communication Commission (FCC). In AMPS, the ESN is made of 32 bits including an 8-bit manufacturer code.
2. A 15-bit system identification (SID) to identify the cellular operator. It includes a 2-bit international code and a 13-bit system number.
3. A mobile identification number (MIN), which is a 34-bit sequence that contains the MS's ten-digit telephone number. It includes MIN1 (24 bits corresponding to the seven-digit number without area code) and MIN2 (10 bits corresponding to a three-digit area code).

One more parameter used in AMPS control channels is the station class mark (SCM). It is used for the following purposes:

1. It conveys information on MS's maximum deliverable effective radiated power (ERP). Each of the eight power levels is coded in a three-bit sequence mobile attenuation code (MAC).
2. It tells whether discontinuous transmission (DTX) is used; that is, if a mobile can use voice activity detection (VAD) to switch to a lower power level during idle periods.
3. It provides information on bandwidth (BW) utilization by the MS.

AMPS Control Channels

Stand-alone control channels: An AMPS mobile when not in *active* conversation mode is required to monitor a forward control channel (FOCC) for any possible orders coming from the base station, including paging signals (calls coming from the network). The MS also can use a reverse control channel (RECC) if it has to communicate control information while it is in idle mode. This channel is shared with other MSs using random access. Both control channels operate at 10 kbps.

The FOCC includes streams of control data multiplexed in time division multiplexing (TDM) fashion: channel A, channel B, and a busy/idle channel. Note that A and B are just labels; these channels are unrelated to frequency bands A and B mentioned earlier. An MS will use either channel A or B depending on the least significant bit (LSB) of its MIN. The busy/idle channel indicates whether the RECC is being used. This helps to avoid collisions in this channel.

Tone channels: In addition to the dedicated control channels, AMPS uses tones for control purposes, namely a supervisory audio tone (SAT) and a signaling tone (ST). The SAT is added to each FVC, and the MS uses this same tone on the RVC. It provides a handshake mechanism between the MS and BS to confirm that the MS is tuned to the right channel, especially during handoff. The ST signal, on the other hand, has many purposes: it is used to request to send data from the keypad during conversation, to indicate that an MS

Figure 2: MS state transition diagram

has been alerted and is not yet responding during call pages, and to initiate termination of calls from users. Furthermore, the ST is also used during handoff for confirmation purposes.

Associated control channels: In addition to these dedicated control channels, the analog FVC and RVC may be “blanked” and used by an associated control channel labeled appropriately *blank* and *burst* channel. This is a digital channel transmitted at 10 kbps and using frequency shift keying (FSK). To allow the receiver to recognize and synchronize with the data burst, a *dotting sequence* (a sequence of alternating ones and zeros) is transmitted first, followed by a synchronization preamble that precedes the real control data.

AMPS Call-Processing Procedures

A mobile needs to register with the system as soon as it powers up or arrives in a new system.

This procedure is called autonomous mobile registration. The following steps summarize the actions of an MS and a BS during this initialization stage. Note that call processing procedures are similar in most cellular systems; only details of the control channels used differ from one system to another. The general idea of call processing is the same and will not be revisited when other standards are discussed. Figure 2 shows the state transition of a mobile upon power-up. Note that the access state is a transition state after which the MS must go into conversation mode; otherwise, it goes back to initialization.

Initialization

1. Upon power-up, the MS enters the *receive system parameter* state and determines whether system A or B is going to be used.
2. The MS scans all twenty-one forward control channels, tunes to the channel with the strongest signal, and receives and updates operating parameters and SID. It also identifies which service provider and paging channels will be used.
3. The MS uses the RECC to identify itself to the network, and registers in the network by sending its MIN, ESN, and SID.
4. Upon reception of FOCC message verifying registration information, the MS enters the *idle state*.
5. In idle state, the MS monitors the FOCC for any paging messages and uses this channel as well as the RECC to

keep it synchronized with the system, and to inform the network of its mobility parameters.

Call initiation and reception. When idle, the MS can have a call connected either after being paged by the BS, or when the user originates a call. The call origination state is entered when the user dials a number and presses the send button, in which case the MS goes into the following call processing steps. These steps are a summary of a detailed enumeration by Black (1998).

1. The MS sends an origination message containing its own MIN and ESN and the destination's MIN to BS using the RECC control channel.
2. Using ANSI-41 protocols, the BS, via Base Station Controller, passes the MS's request for connection to the MSC, which relays it to the external network.
3. The BS uses the FOCC control channel to order the MS to tune to some specific RVC and FVC.
4. The BS and the MS both switch to their respective voice channels.
5. The BS sends an SAT signal on the FVC.
6. The MS responds with an SAT signal on the RVC.
7. An answer from the network is received and the conversation starts.

A page signal that is coming from the BS means that a call is generally coming from an external switch and is requesting a connection with the MS using ANSI-41. Similar steps are followed in this case, with one difference: the BS pages the MS on the FOCC, the MS responds with a page response on the RECC, and then the BS switches to FVC and asks the MS to tune to the specific FVC and RVC channels. Then SAT signals are exchanged until the user responds to the rings and starts the call.

Call termination. Upon call termination, the MS goes back to initialization state. Call termination is a procedure that can be triggered by many events including the user, the called party, or the network. Successful call termination has always been an issue in cellular design because it affects customer billing. It may be as important as service parameters such as probability of successful connection. Call termination can be triggered by the serving MSC as a result of one of the following events: called party busy, no page response, no answer, not reachable, or routing failure. Termination can also be triggered by the originating MSC upon incoming call redirection. More information about this issue can be found in the ANSI-41 standard (ANSI/TIA/EIA, 1995).

Second-Generation Cellular Systems: IS-54/IS-136, IS-95, and GSM

The main difference between the first- and second-generation cellular systems is that the first generation was based on analog signals using FDMA, whereas the second-generation and third-generation systems use digital signals for voice, data, and control. 2G and 3G systems also use a combination of one or more of time division multiple

access (TDMA), FDMA, and code division multiple access (CDMA) as multiple access methods. This allowed the second-generation systems to manipulate digital data in ways that were not possible with analog signals. These included:

- Encryption of data for privacy
- Channel coding to correct errors
- Source coding to take advantage of redundancy and minimize bandwidth requirements
- Spreading the spectrum to combat interference and fading
- Other newly introduced methods that increased efficiency and capacity and decreased the cost of communication.

Despite the declared goal of global interconnectivity, the second generation still suffered from a number of competing incompatible systems, all of which eventually had to coexist. The main second-generation standards currently in use are

1. One standard based on spread spectrum: CDMA, known as cdmaOne or IS-95
2. Two different TDMA standards: IS-136 (for North America and other niche markets) and GSM (for most of the globe)

In the mid-1990s an intense battle raged between the respective proponents of IS-95 and GSM as to whether IS-95 could deliver its initial declared capacity goals, which are ten to forty times stronger than the three-times capacity initially specified by international organizations. A decade later, a few arguments still remain regarding which system is better, but the reality "on the ground" perhaps proves these to be moot. None of the systems were as ideal as advertised, and all three standards required major enhancements and improvements to the initial versions, either in the physical layer or in voice coding, to achieve acceptable capacity and voice quality. It is, however, undeniable that CDMA and orthogonal frequency division multiple access (OFDMA) are ideally superior technologies if their theoretical capacity limits are reached. The arguments of the opponents of IS-95 did not contradict this. They merely stated that IS-95 was not mature enough for a second generation and that it would have been better to wait and introduce it as a third generation.

The section entitled "Principles of Cellular System Design" emphasizes the GSM TDMA standard as the main example of 2G cellular systems. However, IS-136 (also using TDMA) and IS-95 (using CDMA) have many differences, which are listed in the following two subsections.

IS-136 (North American Digital Cellular)

IS-136 was an evolution of the D-AMPS system that was adopted in 1991 as the IS-54 standard, but did not really take off in many markets. IS-136 can use the personal communication system (PCS) band in North America (1900 MHz) as well as the traditional cellular band (800 MHz).

Table 3: Logical Control Channels of IS-136

Logical Channel	Function	Physical Channel
FDTC/RDTC	Forward/reverse digital traffic channel: user information and signaling	Digital traffic channel (DTC)
FACCH	Fast associated control channel: burst short-term signaling	DTC
SACCH	Slow associated control channel: long-term continuous signaling	DTC
RACH	Random access channel: used by MS to gain access to system	Dedicated control channel (DCCH)
PCH	Paging channel: used by BS to page the MS	DCCH
ARCH	Access response channel: used after access request by MS	DCCH
SMSCH	Short message service channel: used for SMS on DCCH	DCCH
F-BCCH, E-BCCH, S-BCCH	Fast, extended, and SMS broadcast control channel: control channel broadcast by BS to all MS for various purposes	DCCH
SCF	Shared channel feedback: used by BS to control RACH access	DCCH

Table 3 lists the logical channels used by IS-136 and their use.

The physical layer of IS-136 also differs from that of GSM or IS-95 in the modulation schemes, channel coding, and many other aspects, even though the same general concepts are used. In particular, the following features are noted:

- Frequency division: IS-136 assumes the same carrier frequencies and the same carrier separation as AMPS; however, each frequency is potentially shared by six users (half-rate vocoders) or three users (full-rate vocoders) using TDMA.
- Time division: channels are divided into six time slots and a full-rate user is assigned to either slots 1 and 4, or 2 and 5, or 3 and 6.
- Channel coding: Voice traffic uses two layers of error protection: CRC for the 12 most important bits (Class I) and a convolutional encoder for these bits and the 77 next most important bits. The least important 82 bits do not have any error protection. This approach results in the generation of 260 bits for every 159 *source bits*. These bearer channel bits are then transmitted in the assigned time slots.

IS-95 cdmaOne Basics

In this section, an overview is presented of the IS-95 physical layer details for traffic and control data, including block diagrams of the reverse and forward traffic channels. The reader is referred to Schwartz (2005) and Steele, Lee, and Gould (2001) for more detail. The physical layer design of CDMA-based systems is very different from that of TDMA systems and is quite elaborate. More details about the concepts used by CDMA physical layer technology are found in the sections entitled “Physical Layer Transceiver Technologies” and “GSM Network Architectures, Services, and Interfaces.” Here, we simply highlight the main features of CDMA technology and contrast them with the other 2G systems. Readers who are unfamiliar with the concepts such as channel coding, rake receivers,

fading, and so forth are advised to read those tutorial sections in parallel.

The concept of spread spectrum. The IS-95 standard uses direct sequence spreading: each bit sequence, with a bit period T_b , is modulated by a pseudo-noise (PN) sequence running at a much higher rate, the *chip* rate = $1/T_c$. The processing gain (PG) is the bandwidth spreading ratio and is equal to T_b/T_c .

PN sequences are named this way because they are “almost” random. They actually are generated using feedback shift-registers, which generate periodic sequences that would look random for a receiver that does not have the same code used by the shift registers in the transmitter. Different PN sequences are *pseudo-orthogonal* (almost orthogonal); in other words, demodulation of the received spread signal using anything but the correct PN code used in the transmitted will result in an output signal that is close to zero (if it is exactly zero, the codes are called orthogonal).

Initially introduced in the military, spread spectrum had obvious benefits only in applications in which there was no limitation on bandwidth and a bigger need for jamming and interference avoidance. CDMA became feasible as a multiple access scheme for cellular systems primarily because IS-95 introduced a few tricks to increase its capacity. These tricks include closed-loop power control (see the section entitled “Physical Layer Transceiver Technologies”), and a significant amount of coding and spreading activity, as well as a relatively complicated rake receiver. This is a customized equalizer-type receiver with diversity combining that takes advantage of, rather than suffering passively from, multipath. One more feature of IS-95 that was not possible with TDMA-based systems is the use of *soft* handoff, a handoff procedure in which the MS gets connected with two or more BSs and combines the signals it receives from all of them, thus achieving better reception in the weak coverage areas at the edge of the cells. More technical details about such physical layer features of IS-95 are covered in the following two sections.

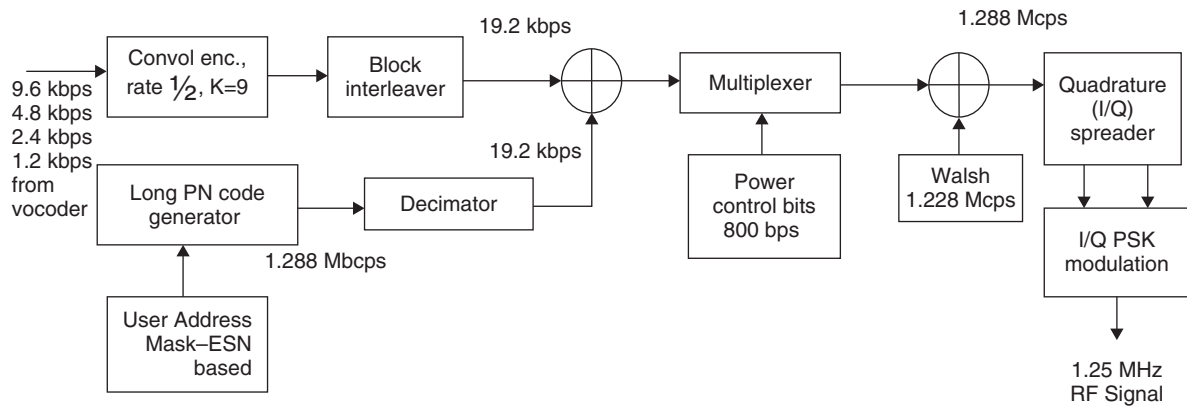

Figure 3: Forward link block diagram of IS-95 (Note that input bits are already partially CRC-encoded and have a variable bit rate according to voice activity; only the maximum data rate is shown here)

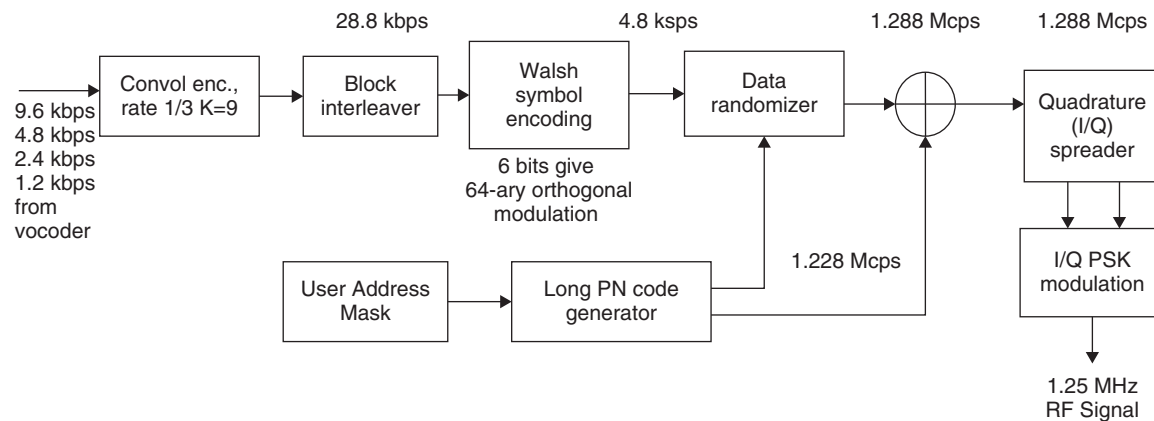

Figure 4: Reverse link block diagram of IS-95 (Note that input bits are already partially CRC-encoded and have a variable bit rate according to voice activity; only the maximum data rate is shown here. For explanation of symbols and terms, refer to the section entitled “Physical Layer Transceiver Technologies” and the text in this section.)

Block diagram of the physical layer of IS-95 traffic channels. Figures 3 and 4 show a block diagram of the main functions of the IS-95 transmitters in the forward and reverse links. They also include some major technical details of the major transmitter and receiver stages (for details, please consult Schwartz 2005; Steele and Hanzo 1999). Some technical details of the major transmitter and receiver stages are included in these figures. A brief explanation of the different stages follows.

Vocoder output. The data rate coming from the vocoder and going into the channel encoder (convolutional encoder) is augmented by a 12-bit/frame cyclic redundancy check (CRC) and an 8-bit tail sequence. The CRC redundancy is used for error detection, and the tail bits are needed for the nine-stage shift registers used by the convolutional encoder and are discarded after decoding in the receiver. This makes the 8.6 kbps original data stream a 9.6 kbps channel. Note that this corresponds to only one vocoder rate (Rate Set 1). There is also a higher vocoder rate (Rate Set 2), which gives an output bit rate of 14.4 kbps instead of 9.6 kbps.

Convolutional encoder. A rate 1/3 coding means that three output bits are generated for every input bit. $K=9$

is the constraint length, which signifies how far back in the bit sequence the encoder must go to generate the current bit. It is basically the number of shift register stages used. After convolutional coding, some relatively unorthodox methods are used in the forward link to make the higher rate data fit into the same 19.2 kbps channel bit rate, namely, a severe *symbol puncturing* where one-third of the symbols are eliminated! In the reverse link, rate 1/2 encoding is simply used instead of rate 1/3 encoding, thus achieving a bit rate of 19.2 kbps after this stage. It should be noted that this puncturing does not necessarily result in loss of data because the channel-coded symbols carry a lot of redundancy.

Block interleaver. Most channel coding schemes are not able to correct errors that come in bursts, so separating the errors into different blocks of data makes it easier for the decoder to eliminate those errors. The block interleaver shown in the figure achieves this function. This is a device that enters the bits into an 32×18 matrix (one column at a time) and outputs them one row at a time, thus uniformly spreading out each block of 32 consecutive bits in a larger block of 576 bits. Thus, if some bursts of errors occur in the channel, they are separated in the receiver after de-interleaving and before error correction.

Power control bit multiplexing. Power control bits are inserted instead of information bits at a rate of 800 bits per second. This is done just before the Walsh function spreading. These power control bits tell the MS to either raise or lower its transmitting power by 0.5 dB or 1 dB. For information on how and where the bits are multiplexed, see pages 225–231 in Steele, Lee, and Gould (2001).

Long and short PN code generation.

1. A long PN sequence of period 2^{42} is used in many steps in the forward and reverse link. One such use in the reverse link is the DS spreading and user identity. Another use in the forward link is to generate a decimated sequence that would be added to the bit sequence for scrambling purposes.
2. A short PN sequence of length 2^{15} is used in quadrature spreading, and an offset is introduced in every sequence that is unique for every BS in a cluster, thus minimizing interference from neighboring base stations.

Use of Walsh functions. Walsh functions are periodic and orthogonal functions of time, values of which are generated using rows in a Hadamard matrix of variable ranks (see Viterbi 1995). Orthogonal Walsh functions are used in different ways depending on which direction the traffic is going.

- In the reverse link, the sixty-four orthogonal functions are used as an orthogonal M-ary Modulation tool, generating 4.8 kbps with a pre-DS spreading channel chip rate of 307.2 kcps.
- In the forward link, Walsh functions are used for DS spreading and user identification.

Direct sequence versus quadrature spreading. The term *quadrature spreading* might be thought of as a misnomer due to the fact that the chip rate stays practically the same after this step. However, it is very important in the forward link to reduce interference between signals from nearby BSs that might end up with the same Walsh codes. A different offset between the short-code PN sequences will ensure they are pseudo-orthogonal even if the Walsh sequence was the same. In the reverse link, in addition to the use of quadrature spreading for similar reasons, the long code is used for DS spreading of the 64-ary symbol sequences. Different offsets of this long code determine the user identity, and the ESNs of the mobile units are used to generate these offsets.

Control channels used in IS-95. Table 4 lists the major reverse and forward control channels in CDMA. The use of the control channels is very similar to GSM or IS-136. A pilot channel, however, is needed to achieve code acquisition and phase synchronization. No channel encoding is used for this channel because the information sent is already known (all zeros). Paging channels are usually limited to one or two, but any of the first seven Walsh functions can be used by a paging channel. Note that control channels such as the paging channel have lower information bit rate than voice channels, but the same channel bit rate is used eventually. This allows some extra redundancy to achieve higher link reliability for control data.

Data Service in 2.5 Generation: GPRS and EDGE

The 2.5G standards were introduced to allow second-generation systems to have more efficient and higher bit

Table 4: Overview of Control Channels Used in IS-95 and Their Physical Layer Properties

	Channel Type	Code Used	Data Rate	Channel Encoder
Forward Link BS to MS	Pilot channel	Walsh function W0	All 0s	None
	Synch channel	Walsh function W32	1200 bps	Conv. encoder rate 1/2, K = 9 Symbol repetition and interleaving
	Paging channel	Up to seven channels W1 to W7	4.8 kbps or 9.6 kbps	Conv. encoder rate 1/2, K = 9 Symbol repetition (for 4.8 kbps) and interleaving
	Traffic-signaling and pilot channels	Up to sixty-three traffic channels, W1–W63, but normally sixty-one is the maximum	800 bps pilot channel, signaling	Same as voice traffic (see the section entitled “GSM Network Architectures, Services, and Interfaces” for details)
Reverse Link MS to BS	Access channel Up to thirty-two channels	PN sequence direct spreading	4800 bps	Conv. encoder, rate 1/3, K = 9, symbol repetition, interleaver, Walsh encoding, PN sequence quadrature spreading
	Traffic channel signaling	PN sequence direct spreading; number is interference-limited	Variable (0 to 168 bits out of each 172 bits)	Same as voice traffic (see the section entitled “GSM Network Architectures, Services, and Interfaces” for details)

Table 5: 2.5G Main Features and Upgrade Requirements Compared to 3G (W-CDMA)

	Channel Bandwidth	Data Service	New Hardware Requirement	New Software Requirement
HSCSD	200 KHz	Up to 57.6 kbps	None	At BTS
GPRS	200 KHz	Up to 171.2 kbps	Routers and gateways	Routing SW in MSC
EDGE	200 KHz	Up to 384 kbps	New transceiver at BTS	BSC and BTS upgrade
W-CDMA	5 MHz	Up to 2 Mbps	Completely new BTS	Completely different SW

rate data service than earlier standards. One first attempt at higher data rate was the introduction of high-speed circuit-switched data (HSCSD), which merely increased the connection bit rate in GSM by assigning more than one time slot to each user. The calls remained circuit-switched, with all of the inefficiencies resulting from circuit switching for bursty data traffic. The two main 2.5 generation data service standards that made it past the hypothetical standard development stage and into full commercialization are GPRS and EDGE. The next two paragraphs give a very brief overview of these two intermediate standards. Table 5 shows the main features of 2.5 generation systems, and the extent of hardware and software changes needed to upgrade to it from 2G compared to the features and requirements of 3G.

General Packet Radio Service (GPRS)

GPRS uses packet switching that employs the MSC as a routing switch. Figure 5 shows the protocol stack of GPRS. The fact that the physical layer used in GSM is not affected ensures that no new hardware is needed in the base station, although routing software and hardware are needed in the switch.

The main innovation introduced in this standard other than packet switching, requiring the MSC to be a router (labeled SGS in Figure 5), is multiple data classes with various quality of service (QoS) requirements. These classes range from 1 (with mean delay less than 0.5 s and 95 percentile delay less than 1.5 s) to 4 (best-effort traffic

with unspecified delay). Note that delay here accounts for the time it takes the data to traverse the mobile network only, not the external networks. Other QoS parameters are data integrity (BER) and requested throughput. To ensure that these Quality of Service (QoS) parameters are satisfied and that correct priority is given to the correct classes of traffic, some second-layer protocols are introduced. The second layer of the protocol stack in the GPRS architecture (data link layer) is divided into three sublayers: logical link control (LLC), radio link control (RLC), and MAC. The last two layers are specific to the radio interface, and they are primarily tasked with allocating channels and maintaining link integrity between MS and BS (see Schwartz 2005 for details). Principles of communication protocol stacks are discussed in more detail in other chapters of this handbook.

Enhanced Data Rates for GSM Evolution (EDGE)

EDGE is proposed as an enhancement on GPRS and IS-136 to achieve higher data rates not possible with GPRS. Minor changes in the physical layer are introduced, such as the use of 8-PSK modulation instead of Gaussian minimum shift keying (GMSK), thus increasing the possible bit rate by a factor of three. An EDGE time slot has the same length as that of GSM—namely, 0.577 ms. However, 116 symbols are transmitted, carrying the equivalent of 69.6 kbps per time slot. If eight time slots are allocated for one connection, the maximum data rate achievable is 557 kbps. This is within a comparable range of values for 3G. However, in practice EDGE might not allocate

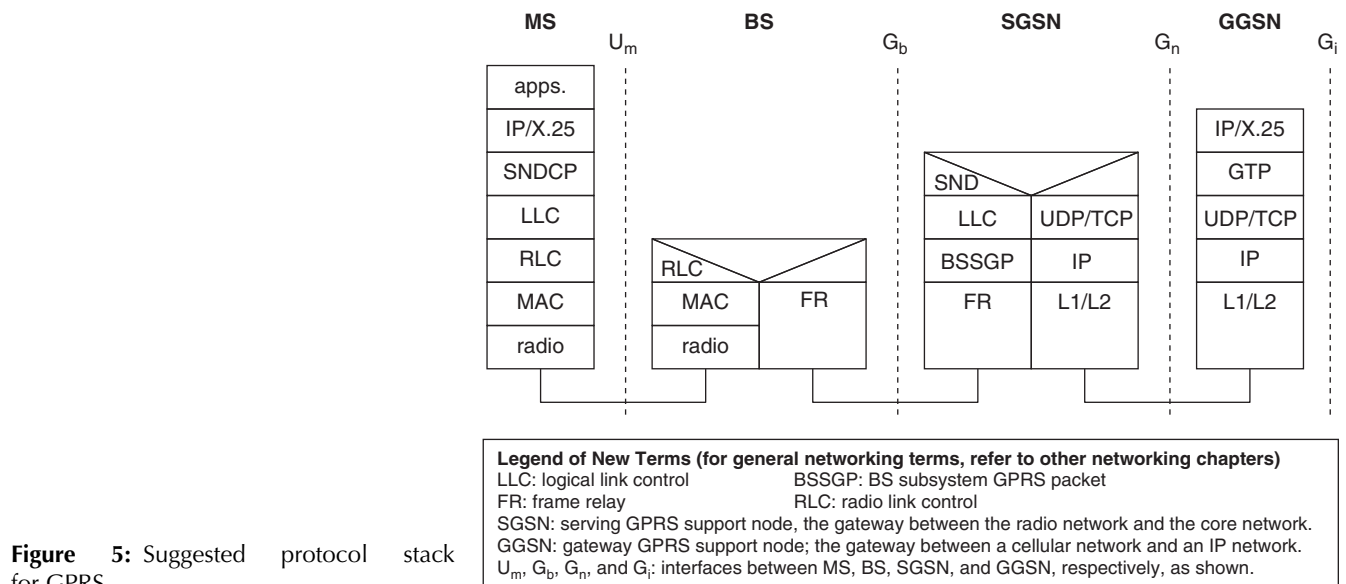

Figure 5: Suggested protocol stack for GPRS

more than 384 kbps for static users and 144 kbps for mobile users.

3G Systems: The UMTS Example

3G Evolution and Standards

Despite efforts to develop a *universal 3G* system that is accepted globally, 3G systems could not be unified. 3G systems were adopted and were practically incompatible unless mobile units were designed to have practically three phones in one. Ironically, all third-generation standards adopted very similar technologies based on direct spreading of CDMA. In North America, the CDMA2000 standard development activity under the 3G Partnership Project (3GPP2) organization initially split into two backward-compatible technologies, 1xRTT and 3xRTT. Having evolved from IS-95, their standardization work was initially under the label of IS-95C. 1xRTT later evolved into 1xEV-DO. According to the 3GPP2 Web site (2006), as of the year 2006, CDMA2000 is “the most widely deployed 3G technology with 51 CDMA2000 1xEV-DO systems, serving more than 300 million subscribers.”

In Europe and much of the world, however, a new wideband CDMA technology that is incompatible with previous North American standards has been introduced: universal mobile telecommunication system (UMTS). Unlike CDMA2000, it uses a 5 MHz bandwidth and is totally incompatible with IS-95. Signaling based on GSM MAP and a network architecture evolving from it has also been adopted for this standard. The 3GPP organization has been using protocols similar to GSM, with a major difference in issues that are particular to third-generation data service, such as radio resource management (RRM) and security (see 3GPP 2001, 2004, 2005). The major aspects of the UMTS physical layer are described in the next two subsections (more details can be found in Holma and Toskala [2001] and in the 3GPP documentation).

The third version of 3G is TD-CDMA, or UMTS-TDD, which has been recently introduced in many countries including Japan, Great Britain, Australia, and South Africa, among others. It differs from the standard UMTS in using TDD instead of FDD to duplex between the forward and reverse links, which allows for variable asymmetric traffic between the directions (UMTS TDD Alliance 2006).

Due to space constraints, only UMTS will be discussed here.

UMTS Physical Layer Features

The following features are introduced with UMTS:

1. UMTS uses the wideband code division multiple access (W-CDMA) standard, which uses direct sequence spread spectrum (DSSS) modulation with a chip rate of 3.84 Mcps (mega chips per second, which is the spread sequence chip rate discussed earlier the chapter).
2. The channel bandwidth is 5 MHz, with benefits such as higher data rates and improved multipath resolution.
3. Error control coding options include rate 1/2 and 1/3 convolutional coding as well as rate 1/3 turbo coding.
4. The supported data rates range from a few kb/s to 2 Mb/s.

5. The physical layer supports two modes of operation: FDD and TDD (mainly in China).

Table 6 lists some of the UMTS/FDD physical layer specifications (see Korhonen [2003] for an extensive treatment on 3G systems).

It is noted that the variable bit rate of UMTS is achieved by using a variable spreading factor using Walsh functions with variable chip period.

UMTS Channels

In UMTS systems, transport channels (channels transporting higher-layer information) are mapped into one or more physical bearer channels. There are also physical channels that carry only physical layer information and do not get mapped to any transport channels.

Forward Link Channels

The UMTS physical layer has variable bit rate transport channels and is designed to offer *bandwidth on demand*. As is the case in second-generation cellular systems, two types of transport bearer channels are supported by UMTS: dedicated channels and shared channels.

Only one type of dedicated transport channel is specified: *the dedicated channel* (DCH). The physical channels treat all information in the DCH equally, whether it is control information (carried in the dedicated physical control channel [DPCCH]) or actual user data (carried in the dedicated physical data channel [DPDCH]). Variable bit rate capability and service multiplexing make these channels the only channels needed for speech, control data, measurements, or even handoff information. These dedicated channels benefit from many physical layer enhancements such as fast power control, data rate change from frame to frame, soft handoffs, and adaptive smart antenna systems.

The following common transport channels are specified:

1. The common pilot channel (CPICH): a continuous downlink pilot signal that is used by the mobile terminal (MT; nomenclature used in 3G instead of MS) as a reference signal for carrier synchronization and channel estimation.
2. The common control physical channel (CCPCH): used to carry several upper-layer transport channels, as well as the forward access channel (FACH) and the paging channel.
3. The synchronization channel (SCH): the first channel that an MT looks for upon start-up; it is a channel that helps the MT receive a sequence used for synchronization.

Reverse Link Channels

1. The DPDCH carries data dedicated for one user. For example, this channel could be used to carry voice traffic as well as audio/video data from a specific user. There can be up to six DPDCH channels.
2. The DPCCH is used to carry physical layer control information associated with the DPDCH. Pilot bits are carried on the DPCCH to aid the base station with

Table 6: UMTS/FDD Features

Frequency band:	1920 MHz–1980 MHz and 2110 MHz–2170 MHz (Frequency Division Duplex) UL and DL
Minimum frequency band required:	~2x5 MHz, Frequency re-use: 1, Carrier Spacing: 4.4 MHz–5.2 MHz
Physical layer spreading factors:	4 ... 256 UL, 4 ... 512 DL
Maximum number of (voice) channels on 2 x 5 MHz:	~196 (spreading factor 256 UL, with Voice coding at 7.95 kbps)
Data type:	Packet and circuit switch
Channel coding:	Convolutional coding, turbo code for high rate data
Receiver:	Rake, modulation: QPSK, pulse shaping: raised cosine roll-off = 0.22
Chip rate:	3.84 Mcps
Maximum user data rate (physical interference limited).	2 Mbps (spreading factor 4, parallel codes (3 DL / 6 UL), 1/2 rate coding), but
Frame length:	10 ms. Number of slots / frame: 15
Handovers:	Soft, Softer, (= interfrequency hard handoff)
Power control period:	Time slot = 1500 Hz rate, power control step size: 0.5, 1, 1.5 and 2 dB (variable), power control range: UL 80 dB, DL 30 dB
Mobile peak power:	Power class 1: +33 dBm (+1 dB/-3 dB) = 2W; class 2 +27 dBm, class 3 +24 dBm, class 4 +21 dBm
Number of unique base station identification codes:	512 / frequency

channel estimation and carrier recovery for the DP-DCH. Channel estimation procedures, which are essential for adaptive receivers, aim at identifying channel effects on the signal. Carrier phase recovery is needed for coherent detection in the receiver (coherent detection is a term that means detection based on knowledge of the phase and/or the frequency of the received signal). Regardless of the number of DPDCH channels, there is always only one DPCCCH.

3. The physical random access channel (PRACH) is used to carry random access transmissions. For example, random access transmissions are used when the MT wishes to set up a connection with the base station in order to place an outgoing call.
4. The physical common packet channel (PCPCH) is a shared channel that carries packet-based data transmissions using carrier sense multiple access with collision detection (CSMA/CD), a protocol in which the MT first senses the medium to see if it is available before transmitting, and retransmits the packet after a random delay when “collision” occurs. This is how Ethernet transmissions operate as well.

3.5G, 4G, and Evolution Path of Cellular Telephony

3G had a very slow start, mainly because it did not offer significant improvements in data rates compared to GPRS and EDGE, and especially when compared with the competing broadband wireless and wireline access technologies. The wireless industry is less interested in producing a new fourth-generation (4G) standard than in really

transforming mobile cellular services. Table 7 shows the lofty goals that 4G aims to achieve compared to 3G (LeFevre and Okrah 2001).

Note that the above parameters are just ballpark figures; the cellular industry is careful not to promise any exact figures. However, many technologists see the goals in Table 7 as reasonable expectations in an eventual fourth generation that may take time to be implemented (Schmitz 2005).

In the meantime, the 3GPP standard group has produced some enhanced standards that many people call 3.5G or even 3.75G. These standards are asymmetric (designed for either the downlink or the forward link) and are geared toward better data service. Two intermediate standards have emerged recently high-speed downlink packet access (HSDPA) and high-speed uplink packet access (HSUPA). They are briefly discussed in the following subsections.

HSDPA

HSDPA is a new cellular telephony protocol that is referred to as a 3.5G technology because it extends W-CDMA capabilities and provides a smooth evolutionary path for UMTS networks, allowing higher data capacity in the downlink (up to 14.4 Mbit/s). HSDPA introduces a new W-CDMA channel, the high-speed downlink shared channel (HS-DSCH), which operates in a different way from existing W-CDMA channels, but is only used for downlink communication to the mobile terminal. Along with the HS-DSCH channel, two new physical channels are also introduced. One is the signaling control channel, which informs the user about the data to be sent on HS-DSCH. The second

Table 7: 4G versus 3G (UMTS) Features

Parameter	3G	4G
Frequency band	1.8–2.5 GHz	2–8 GHz
Core network	IP-intranet, mobile IP support	Integrated mobile Internet backbone
Bandwidth	5–20 MHz	5–20 MHz
Smart antennas and space time coding	limited	standard
Data rate	Up to 2 Mbps (384 kbps deployed)	Up to 20–100 Mbps
Access	W-CDMA	MC-CDMA or OFDM (TDMA)
Forward error correction	Convolutional rate 1/2, 1/3	Concatenated coding scheme
Traffic switching (voice/data)	Circuit/packet	Packet only
Control traffic	Wireless transport channels	IP traffic
Multi-user detection (MUD)	No	Yes

one is a reverse channel, which carries acknowledgements and current channel quality information.

The first phase of HSDPA was specified in 3GPP release 5. Phase one is aimed at achieving peak data rates of 14.4 Mbps. HS-DSCH and the use of adaptive modulation are introduced in this phase. This technology has already been deployed in many countries. The second phase of HSDPA is currently being specified in 3GPP release 6 and is aimed to achieve data rates of up to 28.8 Mbps. It will introduce advanced antenna array technologies using multiple-input multiple-output (MIMO).

HSUPA

HSUPA is a very high-speed data access protocol for the uplink of mobile phone networks, with upload speeds that can reach up to 5.76 Mbps. Unlike HSDPA, it is sometimes considered a 3.75G.

The specifications for HSUPA are also included in the UMTS release 6 standard published by 3GPP. Although HSDPA relies on higher modulation schemes to achieve higher data rates, HSUPA cannot use these schemes because of the power constraints on the mobiles. Thus, a fixed QPSK modulation may be used with higher-rate multiple code multiplexing. HSUPA has already been demonstrated successfully in some countries.

PRINCIPLES OF CELLULAR SYSTEM DESIGN

Concepts of Mobile Channel Fading and Path Loss

Radio propagation results in three main distortions of the RF signal:

1. Large-scale and relatively slow shadowing and path loss: These are big variations in received signal power that are caused by randomly varying attenuation of the signal as most of the radio energy is dissipated elsewhere and only a small part reaches the receiver's antenna. This type of distortion, since it is slowly varying, can be easily managed with power control. However,

severe shadowing of many users in one cell affects overall system capacity, as interference from different BSs limits the power each BS can transmit.

2. Short-term multipath signal fading: This phenomenon results from the self-destructive interference of multiple copies of the same signal traveling in different paths, due to reflections, diffractions, and scattering. This random distortion of the signal may cause severe dispersion of the pulses used, and intersymbol interference may be destructive by limiting the bit rate and increasing the BER. This phenomenon is more difficult to counter than shadowing and path loss. Equalization is normally used to reverse it, if possible. However, modulation methods immune to this type of fading (e.g., as spread spectrum) may be unavoidable when high bit rate transmissions in a mobile environment are needed.
3. The time-varying nature of the channel behavior: Randomly varying Doppler frequency spread caused by the mobility of the MS and/or the surrounding environment makes the communication channel characteristics time vary. An optimal receiver has to adjust to these variations.

Long-Term Shadowing and Path Loss Models

Free space propagation loss. In wireless propagation environments, the signal-received power is affected by the propagation of radiated power in all directions, but the receiver only receives the power captured by its antenna. Path loss from free space propagation is shown to be

$$\left(\frac{P_t}{P_r} \right)_{dB} = -10 \log \left[\frac{\lambda^2}{(4\pi^2)d^2} \right] \quad (1)$$

where λ is the wavelength and d is the distance between transmitter (P_t) and receiver (P_r). The equation assumes omnidirectional propagation. Signals from directional antennas also obey the equation, but the gain introduced by these antennas would vary with the propagation angle.

General path loss formula based on log-normal shadowing model. In reality, free space propagation is not possible in cellular systems because there are always two or more paths between the transmitter and the receiver (one direct and one reflected). Actually, a study of a two-ray model shows that the loss in this case is already proportional to d^4 rather than d^2 (Mark and Zhuang 2003). The random addition of many paths with varying attenuations is modeled often as a *log-normal* distribution for the received power with a path loss exponent n , (the power of d in the formula, between 2 and 4 and even larger for indoor propagation). The model assumes the following equation for path loss $L_p(d)$:

$$L_p(d)(dB) = \overline{L_p(d_0)} + 10n \log \left(\frac{d}{d_0} \right) + X_\sigma \quad (2)$$

where d_0 is the minimum distance between the transmitter and the receiver, X_σ is assumed to be a Gaussian random variable with variance σ , and n is assumed to be a fixed number to be determined along with σ using measurements of transmitted and received power and minimum mean square (MMS) estimation.

Link budget and cell coverage. Link budget planning is a part of the network planning process that helps predict the required coverage, capacity and quality of service requirement in the network. In the forward link direction (the direction from the BS to the MS), the available capacity of a cell is limited by the BTS transmission power (typically 20–40 W), which has to be shared by signals transmitted to all users. The objective of the link budget design is to calculate the maximum cell size under some given criteria such as cell coverage. The above path loss model allows us to compute the probability that the received power is above any value, and thus allows us to determine percentage coverage of a cell of any given size, as will be seen in the section entitled “Coverage and Capacity of Cellular Systems.”

Multipath Fading Models

Due to propagation effects such as multiple reflections of the same signal on stationary or moving objects (scattering and diffractions), multiple images of the same communication signal arrive at the receiving antenna with generally random amplitudes, phases, and delays. The received modulated symbol can thus be modeled as a sum of a random number of such images. In addition, the channel is time varying due to the potential mobility of both the MS and its environment. This means that the random parameters affecting the signal propagation may change in value in any given instant.

Probability density function of received envelope. In the receiver, matched filters are used to maximize the signal-to-noise ratio and detect which signal was received. Matched filters generally are optimal in the presence of additive white Gaussian noise (AWGN) environments, but not in channels suffering from multipath distortions. The performance of the receiver must be assessed after a new probability density function is found for the

resulting multipath signal envelope. It can be easily shown using the central limit theorem (Mark and Zhuang 2003) that the received envelope has either a Rician distribution, when there is a strong line-of-sight component corresponding to a direct path, or a Rayleigh distribution, when no such direct path exists. The performance of various modulation schemes used in mobile communication is then assessed assuming such distributions for the received signal amplitude (see the next section).

Delay profile and time dispersion. A *delay profile* of the channel can be estimated by *sounding* it, which means transmitting multiple narrow pulses (approximations of impulses) and then estimating the average received power at different delays for the same transmitted pulse. The mean delay and mean square delay are then used to estimate how much dispersion the signal suffers. Note that the delay profile could be modeled as a continuous or discrete profile. In the first case, we have a discrete number of possible delays τ_k with average powers of $P(\tau_k)$, where k is between 1 and N , which is now a deterministic number; in the second case, we have an average power $P(\tau)$ defined for all positive τ . In the discrete case, one can compute some statistical parameters for the delay spread:

The mean and mean square delay spread are $\bar{\tau} = \frac{\sum_{k=1}^N P(\tau_k) \tau_k}{\sum_{k=1}^N P(\tau_k)}$ and $\overline{\tau^2} = \frac{\sum_{k=1}^N P(\tau_k) \tau_k^2}{\sum_{k=1}^N P(\tau_k)}$, respectively, while

the root mean square delay is the standard deviation of the delay,

$$\sigma_\tau = \sqrt{\overline{\tau^2} - (\bar{\tau})^2} \quad (3)$$

In the continuous time delay case, the sums above become integrals since $P(\tau)$ is in continuous time.

Note that $P(\tau)$ is a statistical average power density profile over all delays τ . It should not be confused with probability, although a normalized power density profile can be interpreted as an estimate of the probability density function of the delay.

Doppler frequency shifts. As a mobile moves, its speed relative to the BS antenna changes. This causes the speed of the electromagnetic wave that travels between the two antennas to change, which affects the received frequency of the signal. This phenomenon is called the “Doppler shift.” In general, a simple formula can illustrate this concept:

$$\Delta f = \frac{1}{2\pi} \frac{d\phi}{dt} = \frac{f}{\lambda} \cos \theta, \quad (4)$$

where f is the frequency of the signal, ϕ is its phase, and θ is the angle between the direction to the BS and the direction of the velocity of the mobile as illustrated in Figure 6.

Note that Δf is a random variable since both the angle and speed of the mobile are random numbers in general.

Figure 6: An illustration of velocity of a mobile relative to base station antenna

This causes a random frequency error at the receiver, which is changing as fast as the mobile velocity changes.

Coherence bandwidth and coherence time. These are the two most important parameters that affect the performance of a channel-estimating receiver at the input. We define an x -coherence bandwidth as the bandwidth at which the signal preserves an x correlation (e.g., a 0.9-coherence BW means that the signal at this bandwidth still preserves some 90 percent correlation). Generally we specify at least 50 percent coherence BW. Qualitatively, channel coherence time is the time it takes the channel characteristics to change. Quantitatively, it is shown to be inversely proportional to the Doppler spread, Δf . It has also been shown (Mark and Zhuang 2003; Rappaport 2001) that a good approximation of the channel coherence time is $T_c = 0.423/\Delta f$, whereas 90 percent coherence BW is around $0.02/\sigma_v$.

Coverage and Capacity of Cellular Systems

This section gives a brief overview of the main cellular system design methods, including:

- Cell planning using frequency reuse to maximize capacity per square kilometer. Frequency reuse, as the name might suggest, is the process of using the same carrier frequencies in different cells that are separated by a distance large enough to minimize interference between signals coming from these two cells.
- Cell coverage determination.
- Capacity utilization versus grade of service (GoS), which is the QoS metric used for circuit switching, as will be shown shortly.

Frequency Reuse and Cell Planning

Co-channel interference coming from neighboring cells is a major problem that limits the capacity of a cellular system. This is the interference that comes from unwanted signals using the same carrier frequency. Normally a frequency once used in one cell cannot be reused in a neighboring cell if pure FDMA is used. The distance that must separate two co-channel base stations divided by the cell radius is entitled frequency reuse ratio (Q). A hexagonal

Figure 7: An example of hexagonal cell frequency reuse (A cluster of seven is shown; A frequency set assigned to cell D can be assigned again following the direction of the arrow)

cellular system, in which each base station is surrounded by six neighboring base stations in a hexagonally shaped grid, as shown in Figure 7, is used in cellular systems.

In a hexagonal cellular system, one must organize frequency assignment in such a way that the signal-to-interference ratio (SIR) resulting from co-channel interference is minimized for all users. One simple way is to use the hexagonal structure to uniformly allocate N different frequencies in each cluster of cells. This can be done by setting $N = i^2 + ij + j^2$, where i and j are positive integers. Then one can reuse the same frequency set used in a specific cell again in another cell if it is located using the following procedure: moving i cells the direction of the six surrounding base stations, then turning 60 degrees to the left and moving j cells in that direction. It can be shown using simple geometry that the frequency reuse ratio Q is given by the following formula: $Q = \frac{D}{R} = \sqrt{3N}$.

An example of frequency reuse of a set of $N = 7$ frequencies is shown in Figure 1.

In the forward link, the SIR can be written in terms of the signal power S , and the interfering signals arriving from all co-channel base stations, as follows:

$$SIR = \frac{S}{\sum_{i=1}^{i_0} I_i}, \quad (5)$$

where I_i is the power received from the i 'th interferer, and i_0 is the number of co-channel interferers.

When only the first tier of interferers is considered, neglecting interference coming from second and third layers of interferers due to significant path loss, the SIR can be approximated as:

$$SIR = \frac{Q^n}{6}, \quad (6)$$

where n is the path loss exponent. This equation means that the higher the frequency reuse ratio, the higher the signal-to-noise ratio. However, we should also note that the higher N is, the lower the channel capacity per cell. In CDMA systems, for example, a frequency reuse of $N = 1$ can be used because all cells can use the same frequencies.

However, the number of channels per frequency can be very limited due to SIR resulting from nonorthogonal codes between users. As was mentioned briefly earlier in the chapter, nonorthogonal PN codes result in interference from signals other than the wanted signal.

Note that Equation 5 can be used in conjunction with Equation 2 to compute the statistics of SIR levels for mobiles in all locations in a cell. Frequency reuse can then be designed based on worst-case scenarios (MS in the edge of the cell) based on average scenarios or based on an estimate of the average outage probability, where the outage probability is the probability that a mobile has a smaller SIR than the minimum required.

Cell Coverage

The probability that the power received is less than a specific threshold, $P_{th}(\text{dB})$, follows directly from Equation (2) for log-normal shadowing:

$$\Pr[P(d) < P_{th}] = Q\left(\frac{\overline{P(d)} - P_{th}}{\sigma}\right) \quad (7)$$

where $\overline{P(d)}$ is the mean received power at distance d , which is computed by assuming $X\sigma$ averaging to zero in Equation 2, and $Q(x)$ is the Q function that results from integrating the Gaussian density function.

Given a required received power threshold, the average area of the cell in which mobiles get a received signal power over this threshold can then be computed (Rappaport 2001).

Channel Trunking Capacity and GoS

The concept of trunking and GoS. The concept of *trunking* allows a large number of users to share a discrete number of channels, for example, in a cell where each user is allocated a channel among those available on a per-call basis. In a trunked cellular system, when a particular user requests service while all channels (frequencies, time slots, or codes) are already in use, the user is blocked and gets a busy signal. Alternatively, users are allowed to wait for a channel to become free, and then they are blocked after a specific maximum time. In the first case, the Erlang B formula (Mark and Zhuang 2003; Schwartz 2005) is used to determine the relationship between traffic intensity, capacity, and the probability of blocking, which in this case is the designated GoS. Here, traffic intensity is a result of the average projected subscriber activity assigned to the specific cell or sector in question, and capacity is the number of channels assigned to that cell/sector. Generally, the GoS is a requirement on the system based on service provider judgment (which is generally made after studies of customer expectations).

The second queuing scheme can be analyzed using the Erlang C formula, which gives a relationship between capacity, traffic intensity, and the probability of being queued (see Mark and Zhuang [2003] and Rappaport [2001]) for details on assumptions and trunking capacity analysis using these formulas). The main GoS in this case is the probability of finding all channels busy, and the probability that the call is rejected after being queued for a given amount of time.

Cell planning versus trunking capacity. The relationship implied above between a required GoS, the average traffic intensity per cell (or per sector), and the number of traffic channels available per cell (or sector) is an important factor considered in cell planning and channel assignment. Given a GoS and a number of channels, the network planners need to set limits with regard to the number of users in the system, and to manage radio resources optimally to avoid having cells with low GoS and others with idle channels. The reduction of cell sizes to achieve the required capacity per square kilometer may be the only choice if the system as a whole cannot guarantee the required GoS for some cells due to a high density of users.

Channel Assignment Strategies

The previous analysis assumed rigid assignment of channels or frequencies to each cell or sector. In reality, channel assignment strategies are more flexible. Other factors affect channel assignments than frequency reuse and required GoS of new or handoff calls. The choice of channel assignment strategy impacts the performance of the system, particularly the way calls are managed when an MS is handed off from one BS to another.

In a fixed channel assignment strategy, the call is blocked and the subscriber does not receive service if all channels in that cell are occupied. Several variations of the fixed assignment strategy exist. In one approach, called the borrowing strategy, a cell is allowed to *borrow* channels from a neighboring cell if all of its own channels are already occupied.

In a *dynamic* channel assignment strategy, voice channels are not allocated to different cells permanently. Instead, each time a call request is made, the serving base station requests a channel from the MSC. The switch then allocates a channel to the requested cell following an algorithm that takes into account the *likelihood of future blocking within the cell*, the frequency of use of the *candidate channel*, the *reuse distance of the channel*, and other cost functions.

Handoff also needs to get priority in channel assignment since it cannot be queued for long; neither can it be allowed to be dropped often during conversation. Most systems have *reserved capacity* for handoffs (channels that are exclusively used for handoff) in addition to the priority given to handoff calls in the assignment of the other channels.

Techniques to Improve Cell Capacity and Coverage

Cell sectoring. With this approach, the co-channel interference potential is reduced by using three or six directional antennas per base station to divide the cells into three or six geographic sectors. It also increases capacity by reducing the number of cells required in a cluster. However, increasing the number of sectors reduces the trunking efficiency because channels are not generally shared by sectors in the same cell. This implies that there should be a net gain from sectoring for it to make sense.

Cell splitting. Cell splitting is the process of subdividing a congested cell into smaller cells, each with its own base

station and a corresponding reduction in antenna height and transmitter power.

Cell splitting allows a system to increase its capacity per square kilometer by replacing large cells with smaller cells while not affecting the channel allocation scheme required to maintain the minimum co-channel reuse ratio Q , a very tricky task.

As an example, cell splitting may make cells smaller by reducing the power transmitted by a cluster of base stations and inserting base stations in such a way that the radius of each new microcell is half that of the original cells. The transmit power of the new cells can be found by setting the received power at the new and old cell boundaries to be equal, and finding the new required transmit power.

Repeaters. Repeaters are used to cover hard-to-reach areas. They are bidirectional (i.e., they receive and transmit signals to either direction and relay them to further points). This reduces the need to add power in transmitters that would cause more interference to nearby cells. This also improves the percentage of the cell coverage.

Umbrella cells. These are larger cells that are covered by BSs with higher antennas and larger transmission power that coexist in the same geographical region as smaller microcells covered by base stations with shorter antennas and low transmitting power. This has many benefits, the most obvious of which is having faster-moving users (such as mobiles in cars) covered by the umbrella cells to reduce the rate of handoffs, while more numerous but slower-moving users are covered by the more dense network of micro-base stations.

PHYSICAL LAYER TRANSCEIVER TECHNOLOGIES

Modulation and Detection Methods

In second generation systems, various digital modulation schemes are used with variable modulation efficiencies. The main modulation methods that are used in 2G and 3G cellular systems are GMSK and M-PSK, ($M = 2$ gives BPSK, $M = 4$ gives QPSK, and $M = 8$ gives 8-PSK). Multiple quadrature amplitude modulation (M-QAM), a combination of amplitude and phase shift keying, also is used in more recent systems.

The main figures of merit for any digital modulation scheme are bandwidth efficiency (the ratio of channel bit rate to occupied RF bandwidth in b/s/Hz) and energy efficiency (the needed energy per bit to achieve a certain level of bit error rate, given a particular noise and interference level). Both of these factors are analyzed by Rappaport (2001), Goldsmith (2005), and Mark and Zhuang (2003). In the following section, only an overview is given of recent results that are or will be used to improve performance in the physical layer.

Comparing Energy Efficiency of Digital Modulation Schemes

The main modulation schemes used in second-generation cellular are QPSK and GMSK. Energy efficiency is

determined by the probability of bit error given E_b/N_0 the ratio of bit energy to noise. Noise here can be a combination of interference and thermal noise. In the following formulae, coherent detection is assumed (i.e., is that the carrier phase is completely known to the receiver).

QPSK. Note that in QPSK we use four different phases, and one of four signals are sent each carrying one of four possible combinations of two bits.

$$s_i(t) = \sqrt{\frac{2E_b}{T_b}} \cos\left(2\pi f_c t + (i-1)\frac{\pi}{2}\right) \quad 0 \leq t \leq T_b \quad (8)$$

The following equation describe the relationship between E_b/N_0 and the bit error probability for QPSK (Mark and Zhuang 2003; Rappaport 2001).

$$P_b(\text{error}) = Q\left(\sqrt{\frac{2E_b}{N_o}}\right) \quad (9)$$

QPSK has the same BER as BPSK and sends two bits for every symbol. It is therefore one of the better modulation schemes in energy efficiency.

GMSK. GMSK is a special kind of minimum shift keying (MSK) that uses a Gaussian pulse-shaping filter to reduce the BW of the transmitted signal; this is used in GSM. Comparing GMSK efficiency with QPSK may be disadvantageous to GMSK. Its BER performance is hard to compute analytically and is estimated in Equation 10 (Rappaport 2001).

$$P_{b,GMSK}(\text{error}) = Q\left(\sqrt{\frac{2\gamma E_b}{N_o}}\right) \text{ where} \quad (10)$$

$$\gamma = \begin{cases} 0.68 & BT = 0.25 \\ 0.85 & BT = \infty \text{ noG - filter} \end{cases}$$

On the other hand, in terms of BW efficiency, GMSK does have an advantage due to the narrow Gaussian filter used.

Higher M-QAM modulation schemes. Higher modulation rates for M-QAM use multiples phases and multiple amplitudes to achieve a much higher modulation rate (bits per symbol). The BER for M-QAM can be approximated as:

$$P_{b,M-QAM}(\text{error}) = \frac{4}{\log_2 M} Q\left(\sqrt{\frac{3(\log_2 M)E_b}{(M-1)N_o}}\right) \text{ where } M > 4 \quad (11)$$

It obviously has weaker energy efficiency than QPSK (i.e., it needs more signal energy to get the same error rate). However, the gain in bandwidth efficiency makes this an attractive choice when lower signal-to-noise ratios can be allowed.

Bandwidth Analysis of QPSK, M-QAM, and GMSK

For QPSK, with proper pulse shaping, the 90 percent energy BW used (bandwidth in which 90 percent of the signal energy resides) can be around 1.5 times the symbol rate, resulting in a bandwidth efficiency of 1.33 bps/Hz. Comparatively, GMSK depends on the BW of the filter and can have a 90 percent BW of around 0.57 times the bit rate, thus having a BW efficiency of 1.75 bps/Hz. In reality, the modulation technique used in GSM achieves 1.35 bps/Hz, and the one used by IS-95 has BW efficiency of less than 1 before spreading.

Performance in Fading

The formulae shown in the section entitled “Comparing Energy Efficiency of Digital Modulation Schemes” not only assumed coherent detection, it assumed only Gaussian-type noise or interference affecting the signal. This is not the case with Rayleigh fading, and, in reality, the BER versus E_b/N_0 relationship becomes very erratic and random. On average, it becomes less than exponential in nature (geometric or worse), achieving a plateau beyond which any increase in E_b/N_0 will not improve the performance. (Goldsmith [2005] and [2003] provide a detailed analysis on computing the average probability of error in a fading channel, and the reader is referred to these textbooks for the details). In general, fading channels may result in unacceptable performance if not countered by diversity combining (to be discussed next), interleaving (an example of which was discussed earlier in the chapter), or other burst error correction methods.

Diversity Combining Methods

Future cellular systems are expected to achieve a much better BW efficiency and much lower required E_b/N_0 by using transmitter and receiver diversity techniques to overcome interference, fading, and noise. Two examples of such advances are discussed.

Antenna Arrays and Microdiversity

Using multiple antenna arrays, in which the elements of arrays are separated in space, achieves *space diversity*. This assumes that the Rayleigh or Rician fading observed in received signals coming from different antennas is uncorrelated. Combining the signals coming from multiple antennas allows us to take advantage of the independence between the paths to achieve higher performance.

The main diversity combining techniques are:

1. Selective diversity uses the branch with the highest SNR after detecting the signal through each of the diversity branches. A simple procedure, but not fast or optimal.
2. Equal gain combining (EGC) combines all signals equally. Since the SNR is an average of all branches, a sole good branch will be affected by the others. Simplest and quickest of all, yet far from optimal.
3. Maximal ratio combining (MRC) multiplies each of the signals by a variable gain to maximize the SNR. This is the best procedure, but it is iterative and complicated.

4. Scanning (or threshold) diversity combining: sets an SNR threshold and uses the first diversity branch that achieves that threshold or higher. This is a compromise on selective diversity to achieve quicker detection. Variations of these methods would choose the first n diversity branches out of N that would combine to the required SNR using either MRC or EGC.

Distributed Antennas and Macrodiversity

The cited methods are normally used to combine signals that are suffering Rayleigh multipath fading. However, the distance between antennas is in this case assumed to be small (in the order of a fraction of a wavelength). This implies that such multiple antenna systems may still suffer from correlated shadowing and thus any diversity combining might not help increase capacity. Having distributed antennas that are spaced away from the center of the cell allows the signals from different antennas to experience uncorrelated shadowing. This level of diversity (called *macrodiversity*) can achieve much higher capacity levels for 3G CDMA systems in urban environments (Bdira and Mermelstein 1999). Its drawback is the cost involved in distancing the antennas. In microcellular urban environments, however, this scheme may be very feasible due to the smaller size of the cells.

Space-Time Coding and MIMO Systems

In MIMO systems, m transmit antennas and n receive antennas are used to achieve much higher BER performance (Yaun, Chen, and Vucetic 2003). They can also be used to increase data rate through multiplexing, thus achieving very high spectral efficiency gains. The added complexity at the transmitter and the receiver can be prohibitive, though. It is actually equivalent in complexity to an $n \times m$ space diversity system if the channel can be known to the transmitter in *space-only* diversity (Giannakis et al. 2001). A theoretical analysis of space-time codes using MIMO systems can be found in Chapter 10 of Goldsmith (2005).

CDMA Power Control and the Rake Receiver

CDMA is a particular system in which power control accuracy affects capacity, and also in which multipath diversity can be used to increase performance. A brief overview of the peculiarities of CDMA transceivers follows. For readers unfamiliar with spread spectrum, this section should be read in parallel with the section entitled “IS-95 cdmaOne Basics.”

CDMA Channel Model and Rake Receiver

Due to the properties of PN sequences used in spread-spectrum CDMA systems, interference coming from a signal that is modulated using a different PN sequence, or from the same PN sequence shifted in time by more than one chip period, becomes attenuated at the output of the correlator. As a result, the interference power is divided by the processing gain (Viterbi 1995).

The rake receiver takes advantage of this property when frequency selective fading occurs. The chip period in this case is smaller than the multipath spread, so images of the received signal exist in more than one chip and

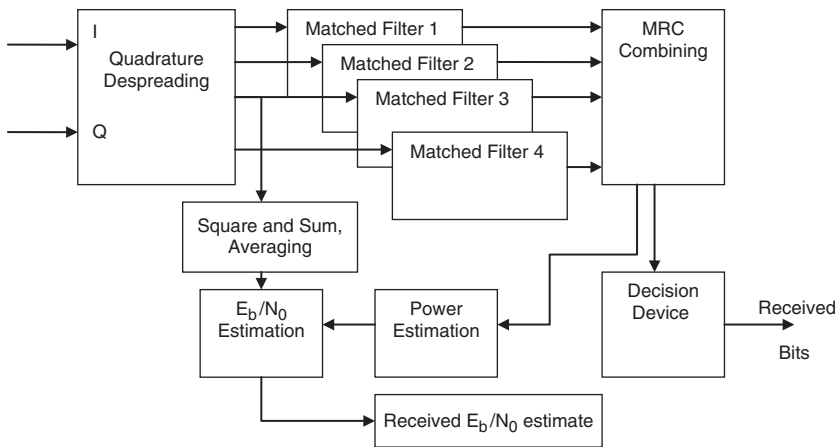

Figure 8: A diagram of a rake receiver with four decorrelators (or matched filters) and E_b/N_0 estimation

thus can be treated as uncorrelated, attenuated versions of the same signal. This allows the signal images to be combined using maxim MRC or EGC. This is done by having multiple decorrelators (or matched filters) using the same PN sequence used by the transmitter, but shifted in time by multiples of a chip period.

Figure 8 shows a simplified block diagram of a rake receiver using four *fingers*. This figure illustrates two concepts.

1. The use of multipath in a diversity combining multiple outputs of four matched filters
2. The estimation of received SNR that is done in parallel, and is used for both power control and to channel estimation in order to achieve optimal combining of the diversity paths

Note that using the central limit theorem, the interference resulting from other users can be modeled as AWGN. This allows the average signal-to-noise ratio after maximal ratio combining to have a *diversity gain* in addition to the processing gain. In Figure 8, two stages in the estimations of SNR can be seen. In the first stage, the four outputs of the despanders are squared and summed to estimate the energy plus noise, before the match filters, and in a second stage the power estimate is computed at the output of the combiner and fed back to be used for the SNR computation.

One example of how diversity combining coupled with MRC combining with distributed transmitting antenna systems in the downlink is presented in a simplified form here. Assuming uncorrelated path losses $L(k)$ from the k 'th paths, $SNR(k)$ being the SNR seen at the k 'th branch, P_s the power of the received signal, and $P(i)$ the total power transmitted by the i 'th interfering base station, ignoring other system and synchronization losses, the total SNR seen after MRC combining can be given by the following simplified equations (Bdira and Mermelstein 1999):

$$SNR = \sum_k SNR(k), \text{ where}$$

$$SNR(k) = \frac{P_s L(k) PG}{\sum_{n \neq k} P(n) L(n) + \sum_m \sum_n P(m) L(n)} \quad (12)$$

PG is the processing gain. Note that as the number of diversity paths increases, the average received SNR after using MRC increases. In the rake receiver, all signal images from paths other than the path of interest to the particular matched filter (or *finger* of the rake) look like Gaussian white noise and are treated as such in the preceding equation. In Equation 12 the first sum in the denominator corresponds to interference coming from signals transmitted to other users in the same cell, and the second sum corresponds to interference coming from other base stations.

Estimation of Received Power and E_b/N_0 in Rake Receivers

Figure 8 shows how the received power and E_b/N_0 can be estimated in the receiver in two stages. Before the matched filters, the signal and noise are squared and averaged to estimate the received power. After the matched filters and the combiner, at which point ideally the signals is emphasized and noise is deemphasized, the output is fed back to the SNR estimator to compute an estimate of the SNR. With MRC, the weights of the different filters are adjusted to achieve a maximum of the SNR.

The following clarifications need to be made, however:

1. Estimation of E_b/N_0 is crucial for proper operation of both downlinks and forward links. First, it is used in power control decisions, as we will see in the next paragraph. Second, it can be used in mobile assisted handoff (MAHO). With MAHO, the MSC/BSC uses the MS's reports of SNR measurements of signals coming from neighboring BSs to make handoff/soft handoff decisions.
2. E_b/N_0 is estimated by collecting measurements of the signal before matched filtering (i.e., before the noise and interference levels are reduced) and after filtering, and this may be done with or without the aid of a training sequence to help with channel estimation.

Power Control Schemes

Power control schemes for CDMA depend on which link (forward or reverse) the signal is traveling.

1. In the forward direction, *open-loop power control* is used in IS-95 to assign power levels unilaterally by the

BS for each signal depending on the information the BS has about each connection in its cell. The BS does power estimation and E_b/N_0 estimation on its side and may use information coming from the MS about the link performance.

2. In the reverse link, a more accurate closed-loop power control is adopted using a power control bit every 1.25 ms (every 0.67 ms for UMTS) in the forward channel. This bit tells the MS to either increase or decrease its power by a fixed or variable power level. A variable (adaptive) power control step size does not necessarily need extra information exchange with the BS. The MS itself may act unilaterally and vary its step size based on statistics of the previous power control bits. Consecutive zeros or ones may suggest that the step size needs to be increased to keep up with rapidly increasing or decreasing received power, whereas alternating ones and zeros may suggest that the step size needs to be decreased to reduce power control errors. A detailed analysis of power control is found in (Steele and Hanzo 1999).

Equalization

An equalizer's goal is to reverse the effect of a multipath channel. In general, equalizers have three categories:

1. Linear zero-forcing equalizers. These equalizers use the discrete impulse response of the channel ($h(k)$) to design a discrete N-tap filter $b(k)$ such that $h(k) * b(k) = 1$ for $k = 0$ and 0 elsewhere around 0. Due to the finite length of the equalizer, only a finite number of time shifts can be equalized.
2. Nonlinear decision feedback equalizers. This type of equalizers has two stages. One stage is similar to the linear equalizer, and the second stage feeds back the output of the decision of the *maximum likelihood detection* device to be used in an N-tap feedback filter to correct any errors in the channel estimation done by the first stage.
3. Adaptive equalizers (linear or with decision feedback). These use variable filter coefficients that adjust with channel variations. Mark and Zhuang (2003) and Goldfield (2005) can be consulted for detail on the fundamentals of equalizer design.

Channel Coding and Turbo Codes

Channel coding in cellular telephony is an essential step to achieve the required BER performance. Unlike optical channels where one could get by with one bit parity check per byte, error protection is much more sophisticated in wireless systems. Second- and third-generation systems use concatenated coding (cascaded codes), hybrid codes combining forward error correction (FEC) with retransmissions (ARQ), and multiple classes of data. The main channel-coding techniques used are as follows:

1. Cyclic redundancy checks (CRC) using BCH and Reed-Solomon (RS) block codes. These are generally (n,k) codes that take each block of k *information* bits (or nonbinary symbols for RS codes) and generate from it

a block of n *code* bits (or symbols). BCH block codes are often used as CRC codes to provide extra protection to the most important class of data, whereas FEC is used for for this class and a second class of important bits. A third, less important class of bits may be transmitted even without FEC.

2. FEC often uses convolutional codes of various constraint lengths and coding rates. Convolution codes use feedback shift registers to sequentially generate output bits that are higher in number and more interdependent than the input bits. A lot of work has been done on these codes in the previous three decades to show their superior performance in error correction. If a code is well designed, the higher the coding rate of a convolutional encoder (output bits vs. input bits), the better its performance. One can also use puncturing with these codes, in which some of the output symbols are *sacrificed* to reduce channel bit rate and still achieve better performance than in the case where the coding rate is lower and no puncturing is done.
3. Turbo coding. This is an advanced parallel concatenated coding technique that also uses interleaving and recursion (the output is fed back to the input). Theoretical bounds on channel capacity can be approached with some turbo codes. However, the receiver for such encoders can get quite complicated, with multiple interleaving/de-interleaving stages and more than one detector stage (Schwartz 2005).

Multi-User Detection Methods

So far, a CDMA receiver was assumed not to know of the interfering signal in a CDMA system and that the sum of all interfering signals can be assumed to be AWGN. With multi-user detection (MUD), receivers know of the interfering sequences and use this knowledge to cancel the interference coming from the other users. The BS in particular can detect all uplink signals simultaneously, thus optimizing interference cancellation and maximizing capacity. An optimal MUD receiver can be prohibitively complex. However, close-to-optimal receivers with reduced complexity can be designed. A comprehensive overview of MUD techniques is presented by one of the pioneers of this field in Verdu (1998).

GSM NETWORK ARCHITECTURES, SERVICES, AND INTERFACES

Introduction

The previous three sections have emphasized physical layer standards and concepts, which are often viewed as the main domains of innovation that allow wireless technology to succeed in its goals. However, issues such as hardware, software, and network architectures are central to cellular system design. This section presents some typical cellular components, interfaces, network architectures, and protocols using GSM as an example.

Mobile Station Elements and Functions

A mobile station (MS) is the user access device to the mobile network and the only user interface for all mobile

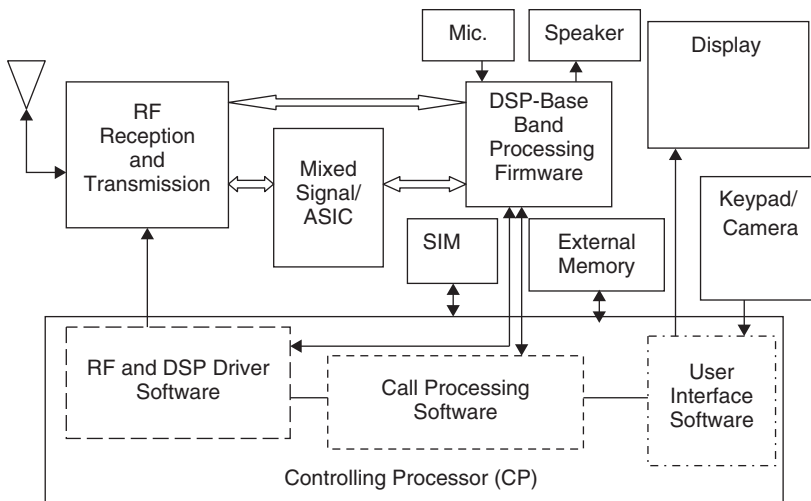

Figure 9: Illustration of the main functions of a mobile phone

applications. It needs to implement all mobile applications and interoperate with any compatible system to ensure that the user obtains access to the promised services. The MS must actually have the counterpart of all functions that are in the BS, MSC, and other network entities. OSI layers supported by these network entities in the data plane, and in the radio-interface control plane, need to be supported by the MS. To do this, the MS typically has the main parts shown in Figure 9 and explained in the following subsections. Sauter (2006) can be consulted on details.

Smart Card (SIM)

The subscriber identity module (SIM) is a smart-chip card that contains a microprocessor chip that stores unique information about the user. Subscribers activate their phones upon insertion of SIM cards.

This detachable module provided by the service provider supports all the terminal/user-specific network interface information (identity, billing, etc.), and the rest of the MS comprises all hardware and software needed for the user interface (UI) and radio interface.

A GSM MS has the following identity parameters stored in the SIM, which is exchanged with the network when necessary:

1. International mobile subscriber identity (IMSI): Stored in the SIM, assigned to an MS at the time of purchase, uniquely identifies a given MS. It contains fifteen digits and includes the following: mobile country code (MCC), mobile network code (MNC), mobile subscriber identification number (MSIN), and national mobile subscriber identity (NMSI).
2. Other parameters are as follows: Authentication key, access control class, cipher key, TMSI, additional GSM services, location area identity (LAI), and forbidden PLMN. These are parameters used for authentication, during registration with home or remote network, and for roaming purposes.

RF, DSP, and Mixed Signal Units

As illustrated in Figure 9, these parts manage most of the physical layer functions in the mobile station.

Including Digital signal processing (DSP), analog RF modulation/demodulation, filtering and amplification (RF board/module), and any steps in between that are hardwired in application-specific integrated circuit (ASIC) chips. Many newer mobile units integrate most of these functions within a single chip.

Controlling Processor Functions

This is the *brain* of the phone, so to speak, and thus exerts all the *intelligent* functions, such as decoding all the upper-layer control and user information, hardware control via drivers, user interface control and response, and overall control of all phone parts and functions to set them to sleep and initiate wake-up, for example. As services using mobile cellular become increasingly data-centric, the processor is required to exert much more effort in upper-layer functions, including security procedures, mobile IP tasks, and application layer tasks.

User Interface Units

User interface functions are becoming more varied and demanding. Initially a phone had a microphone, a speaker, and a simple display/keypad combination to help set up calls and configure the phone. Now, a camera is an input device often added to a cellular phone, and the display is becoming more sophisticated with video graphic array (VGA) video display and Internet browsing requirements. Actually, the user interface is often the limiting factor on the size of the phone. The user interface software functions are dedicated to responding and controlling all the input and output devices of the phone. Unlike call processing, most user interface specifications are not standardized and are left to the manufacturer because they do not affect interoperability between different systems.

Base Station Elements and Functions

The base station transceiver system (BTS) was originally a relaying entity that mainly had RF and DSP transceivers but did not contain many intelligent or upper-layer functions, which are managed by the MSC. It also did not do any source coding or decoding, which are normally done at the BSC or even at the user's end.

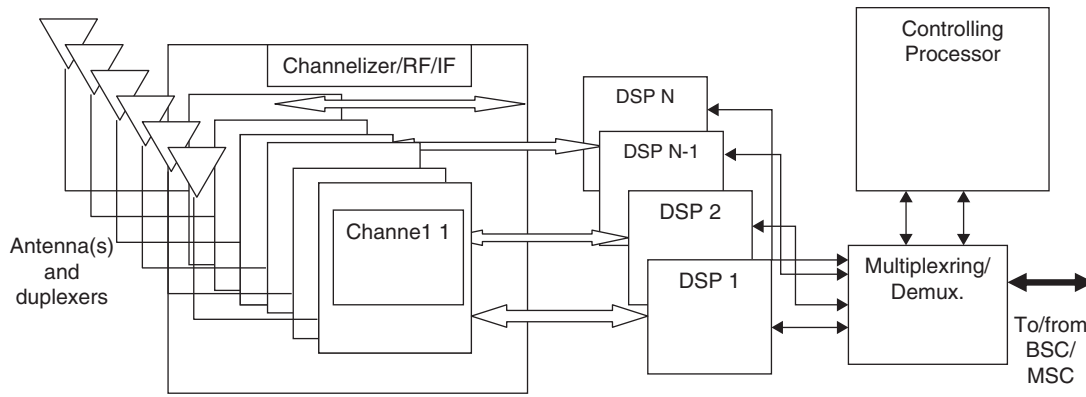

Figure 10: Typical base station transceiver elements

Figure 10 shows a high-level block diagram of a base station. The main components are as follows:

1. The antennas and duplexers at the front end, which receive and transmit signals in both directions. These antennas can either be directional to divide the cells into three or six sectors or omni directional to transmit diversity (see previous sections on cellular system design and diversity). Duplexers are used to provide isolation between the transmitted and received signals in the RF front end.
2. A channelizer is a set of demodulators that separate the received signals from different users into separate baseband channels that are sent to separate DSPs.
3. DSPs are modules that accomplish all the processing needed in the baseband.
4. The controlling processor and associated chips are the intelligent part of the base station because they control all the action and decode any upper-layer messages that are meant for the BS.
5. Multiplexing and demultiplexing of DS0 lines is done also to convert all voice channels into DS0 circuits and back.

Note that in future-generation systems, the BSC functionality may be moved to the BTS. A channelizer may have a different RF receiver for each channel or, in the CDMA case, one or more PN sequence codes for each channel, with a common RF front end.

GSM Land Mobile Network Architecture

Goals of the Land Mobile Network

Some of the goals of the GSM land mobile network are:

1. To provide subscriber services that are compatible with those offered by existing networks (e.g., PSTN, ISDN)
2. To provide these services with various MS types including vehicle-mounted stations, portable stations, and handheld stations
3. To allow connection to the external networks regardless of the location of the MS, including the use of foreign networks (roaming)

4. To allow for a low-cost infrastructure and terminal and to keep cost of service low

Public Land Mobile Network Architecture, GSM Example

It may be ironic that a cellular network is connected with mostly fixed land-based interfaces, and the only wireless interface is the air-interface between the MS and BS (called the U_m interface). The interfaces shown in Figure 11 are all based on wired or fiber interfaces using TDM to multiplex data coming from all channels (data or control traffic) in either a DS1 circuit, an E1 circuit, or other multiplexing standards.

Other than the BTS and MS, the other entities introduced in Figure 11 have the following functions:

The base station subsystem (BSS). The BSS consists of the control function carried out by the BS controller (BSC) and a transmitting function performed by the BTS. A BSS can serve several cells because it can have multiple BTSs. The interface between the BTS and its BSC is called the A_{bis} interface.

The networking and switching subsystem (NSS). The NSS is the functionality that takes care of routing calls to external networks so they get properly connected, in addition to all the networking functions necessary to maintain the security, availability, and quality of service. The entities that are part of this subsystem are the mobile switching center (MSC), the main processing entity of the mobile network, and some specialized databases connected to it: the home location register (HLR) and the visitor location register (VLR), already covered in the overview section. There is also the AUC, a database that stores authentication and cipher keys, and the EIR, which stores information about mobiles including faulty or fraudulent equipments.

The operation and maintenance subsystem (OMS). The OMS is in charge of remote operation and maintenance functions of the PLMN. It may have one or more network management centers (NMCs) to centralize PLMN control. The operational and maintenance center (OMC) is used by the service provider to monitor and control the

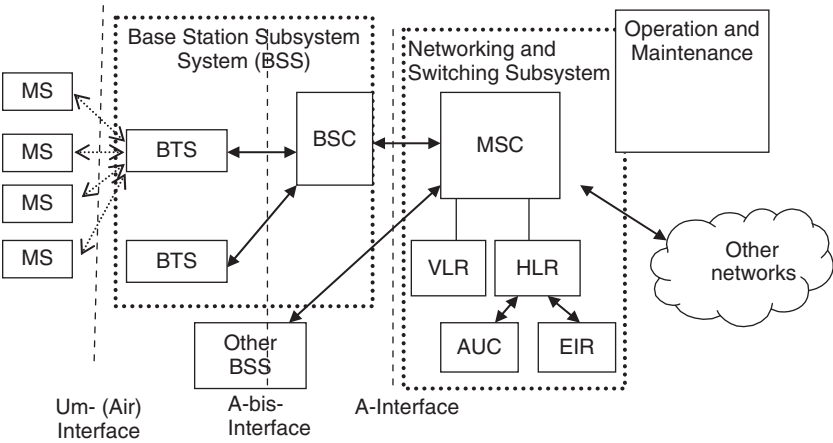

Figure 11: Illustration of a PLMN architecture using the GSM example

system. It is a single point through which the entire system (even multiple MSCs) can be maintained.

More detail about the functions and protocols of all of these entities can be found in the GSM chapter, as well as in *Principle and Application of GSM* by Garg and Wilkes (1999).

Air Interface Protocols: The GSM Example

Introduction

This section gives a brief overview of the protocol stack used for data communication in the air interface. Figure 12 gives a simplified protocol stack for voice and data service in GSM.

GSM Protocol Layers

The U_m interface is the most important interface in mobile communication because it is the only one that is special to wireless communication. Further more, it is usually the bottleneck in the connection to the rest of the world

due to the specific constraints that wireless channels impose on transmission bit rates. This interface has its own protocol stack that includes a physical layer, a link layer usually including a MAC and an LLC, and a radio resource management sublayer, in addition to the other layers or sublayers needed for each specific connection (control, data, voice, or SMS).

The physical layer—interfaces to the data link layer (L2) and radio resource management sublayer (L2) in the MS and BS and to other functional units in the MS, BSS, and MSC to support traffic channels. The physical interface uses a set of physical channels (using an FDMA/TDMA combination). Each physical channel supports a number of logical channels for user traffic and signaling. The physical layer simply takes care of the transmission and reception of bits.

The data link layer role—is multiplexing, error detection and correction, flow control, and segmentation to allow for long messages on the upper layers. A link

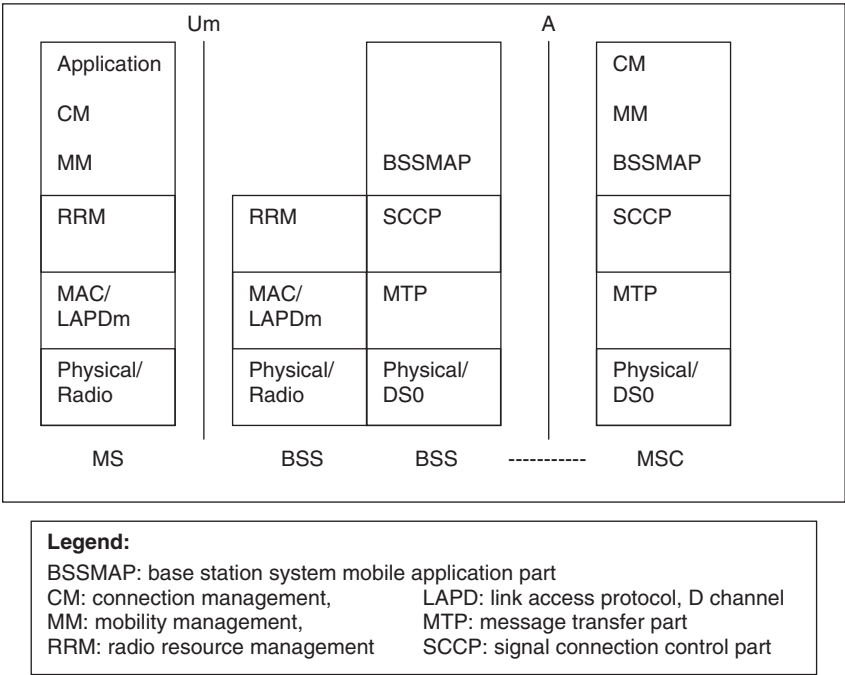

Figure 12: Simplified GSM protocol stack

access protocol is also supported on Dm channel (LAPDm).

The radio resource layer—ensures communication between the MS and BSS concerning the management of the radio connection, including connection establishment and control, call release, and handoff requirements.

The mobility management layer—supports location update, authentication, and encryption management in a mobile environment.

The connection management layer includes:

1. The call control entity, which controls end-to-end call management.
2. The supplementary service entity, which supports the management of supplementary services.
3. The SMS protocol, which supports the high-level functions related to the transfer and management of short message services.

GSM Logical Channels

The following is a brief list of the logical channels used by GSM. All logical channels in the air interface use the same physical channels, given by the absolute radio frequency channel number (ARFCN) and time slots TS0–TS7. A physical channel is one of eight time slots in a single frequency.

1. Speech traffic channels (TCH): full-rate TCH (TCH/F), half-rate TCH (TCH/H).
2. Broadcast channels (BCCH): frequency correction channel (FCCH), synchronization channel (SCH), broadcast control channel (BCCH). These channels usually multiplex within the same slot in a designated frequency. The SCH and FCCH are the first channels the MS looks at when it attempts to register to a new wireless network.
3. Common control channels (CCCH): paging channel (PCH), random access channel (RACH), access grant channel (AGCH), similar to the ones covered in the earlier section entitled “Overview of Cellular Telephony Standards” for other standards.
4. Cell broadcast channel (CBCH), which uses the same physical channel as the DCCH.
5. Dedicated control channels (DCCH): Stand-alone dedicated control channel (SDCCH), slow associated control channel (SACCH), and fast associated control channel (FACCH). The last two are channels used to communicate control information while a call is in progress.

SOURCE CODING FOR VOICE

Source coding aims to represent the source information using a digital sequence that has the lowest bit rate possible while achieving the best possible voice quality. This is done by exploiting the redundancy that naturally exists in most multimedia signals including voice, video, and some data files. JPEG and MPEG standards are known

algorithms that achieve very big compression ratios for still and moving pictures, respectively. With voice, many algorithms have been developed and many standards adopted.

Note that source coders are only one subset of the general group of speech coders, which includes vocoders and waveform coders (see Chapter 8 of Rappaport [2001] and the other references that it cites).

Following are the three general families of vocoders used in second-generation cellular; they are all linear predictive coders (LPC). (See Steele and Hanzo [1999] for a detailed description and analysis of these codecs).

1. Vector-sum excited linear prediction codec), which is used by IS-136. (See Steele [1993] for details).
2. QCELP, a variation of CELP produced by Qualcomm for IS-95 (Wang 1999).
3. LPC-RPE, adopted by GSM after comparisons between many algorithms using a subjective testing study.

UMTS uses the same vocoder as GSM. However, there are many studies suggesting the use of voice over IP, especially for future generations, as wireless networking becomes dominated by IP traffic.

CONCLUSION

This chapter has presented an overview of cellular telephony and the state-of-the-art technology available as of the printing of this handbook. Some tutorial sections on the principles of cellular system design are included for novice readers. There was no attempt to cover other wireless technologies such as fixed wireless access technologies, wireless LANs and PANs, and the newly evolving mobile broadband access. Other chapters in this handbook can be consulted on such subjects.

GLOSSARY

ARFCN: Absolute radio frequency channel number: GSM carrier frequency number.

AUC: Authentication center. A database used by the MSC for encrypting and authentication purposes.

BCCH: Broadcast control channel: A logical channel used by the BS to broadcast control messages to all mobiles.

BER: Bit error rate: The probability of error in the detection of a bit.

BS/BTS: Base station/base transceiver system: The equipment used in each cell to transmit and receive signals to and from the mobiles and relay them to and from the rest of the network (MSC, etc.).

CDMA: Code division multiple access: A multiple-access scheme in which users are identified via codes.

CRC: Cyclic Redundancy Check.

D-AMPS: Digital AMPS: Same as IS-136/54: North American TDMA-based standard.

DCCH: Digital control channel: A channel used to transmit bits that carry control messages.

ESN: Electronic serial number: A sequence of bits stored in memory in the phone and embedded in the IMSI that is unique to every mobile phone.

FACCH: Fast associated control channel: Control bits that are transmitted by taking over whole time slots that are originally allocated to voice traffic. Used when immediate information needs to be sent (e.g., handoff).

FCCH: Frequency correction channel: A control channel used for frequency correction.

FDD: Frequency division duplex: Full duplex system in which the forward link uses one frequency band and the reverse link uses another.

FDMA: Frequency division multiple access: Distributed users sharing a medium by using different frequency bands.

FECC: Forward error correction: A redundancy scheme that allows some errors to be corrected at the receiver without need for retransmission.

FVC: Forward voice channel: A logical channel that carries voice bits in the forward direction (BS to MS).

GPRS: General packet radio service: A 2.5-generation packet data service that uses the same physical layer as GSM but with modifications in upper layers to allow packet switching in the MSC.

GSM: Global system for mobile communication, initially “Groupe Spécial Mobile.” Second-generation TDMA-based digital cellular system.

HLR: Home location register: A database containing information about local subscriber MS's and their main “care of” address used in routing calls when away from their home network.

HSDPA: High-speed downlink packet access. A 3.5-generation cellular enhancement allowing higher data rates in the downlink.

HSUPA: High-speed uplink packet access. A 3.5-generation cellular enhancement allowing higher data rates in the uplink.

IMSI: International mobile subscriber identity: A permanent number assigned to a subscriber mobile and stored in the SIM that includes its MIN and other crucial information used to authorize connections.

MAC: Medium access control: A second layer protocol providing logical channel access.

MAHO: Mobile assisted handoff: A protocol in which mobiles are active in the handoff process, providing information used by the MSC to decide on handoff.

MRC: Maximum ratio combining: A diversity combining method that maximizes SNR.

MSC: Mobile switching center: The main switching and networking entity and the “brain” behind it all in PLMN decisions related to call processing, channel assignment, handoffs, location and mobility management resource management, routing ... you name it!

PN: Pseudo-noise: Digital sequence that is usually generated using a sequence of shift registers. It is periodic but its period is long enough to consider the output sequence almost random, thus the word *pseudo-random*. Used in CDMA and any instances that require use of a recoverable random sequence.

QPSK: Quadrature phase shift keying: A digital modulation scheme that uses four different phases. Variations include $\pi/4$ -QPSK, DQPSK (differential QPSK), OQPSK (offset-QPSK), and $\pi/4$ -DQPSK (Used in IS136).

RACH: Random access channel: A reverse control channel used by all mobiles to request a connection. Random access (ALOHA) is used as the multiple-access mechanism.

RVC: Reverse voice channel: A logical channel that carries voice bits in the reverse direction (MS to BS).

SACCH: Slow associated control channel: Control bits associated with the voice connection (bits in the same slot as voice bits) carrying less urgent information than FACCH.

SCH: Synchronization channel: One of the control channels used for synchronization purposes.

SIM: Subscriber interface module (or subscriber identity module): A small unit containing information such as IMSI and subscriber information used by the phone to call authorization and billing.

TCH: Traffic channels: As opposed to control channels, all channels carrying user data.

TDD: Time-division duplexing: Full duplex system in which the forward link uses one time slot and the reverse link uses another.

TDMA: Time-division multiple access: Distributed users sharing a medium by using different slots.

TMSI: Temporary subscriber identifier: Temporary identity assigned by a host network via its VLR.

UMTS: Universal mobile telecommunications system: 3G cellular system using CDMA that has packet switching for data up to 2 Mbps.

VLR: Visitor location register: Stores temporary local copy of subscriber information of all mobiles registered to its associated MSC(s).

INTRODUCTION

Wireless communications has experienced explosive growth over the last few decades, especially the cellular communications (for details, see “Cellular Telephony”). The first-generation cellular systems emerged in the 1980s, and the systems were analogue and voice centric. Those systems were typically limited in capacity. The second-generation cellular systems appeared about 10 years later with improved capacity, and were digital and voice centric with limited data capacities. Because the second-generation systems were not capable of supporting high bandwidth applications, third-generation systems were developed to support multimedia services such as audio, video, real time video conferencing, and high-speed Internet connections (for details, see “Evolution of Mobile Cellular Networks”). In addition to cellular networks, other wireless networks have also emerged, such as Wireless Local Area Networks (WLANs) (for details, see “Wireless LANs (WLANs)”), Wireless Wide Area Networks (WWANs) (for details, refer to “Wireless Wide Area Networks (WWANs),” wireless ad hoc systems, wireless sensor networks (for details see, “Principles and Applications of Ad Hoc and Sensor Networks”), etc. Next-generation communications systems are expected to integrate various communications networks, support fully integrated services, and provide full coverage and ubiquitous mobile access.

Mobile radio communications refers to transferring information through electromagnetic signals over a wireless radio channel between mobile users. In contrast to the wireline channel, the wireless channel is random and time-varying. As a signal is propagated over the air, the signal may get reflected, diffracted, or scattered. Therefore, the received signal at the receiver usually consists of multiple components corresponding to each distinct path. Because each multipath component has different attenuation gain and delay, the addition of multipath components may contribute constructive or destructive interference, which makes the received signal unpredictable. In addition, when the transmitter, the receiver, or the surrounding objects move, the multipath changes over time, which makes the wireless channel random and time-varying. Due to the nature of wireless channels, the design of wireless systems is fundamentally different from that of wireline systems. (For more details about wireless channels, see “Wireless Channels” and “Cellular Communications Channels.”)

The basic elements of mobile radio communications systems are shown in Figure 1. Most communications systems today are digital systems. The digital signals may come directly from digital sources or may be converted from analog signals through the Analog/Digital converter. The source encoder aims to remove redundancy of the

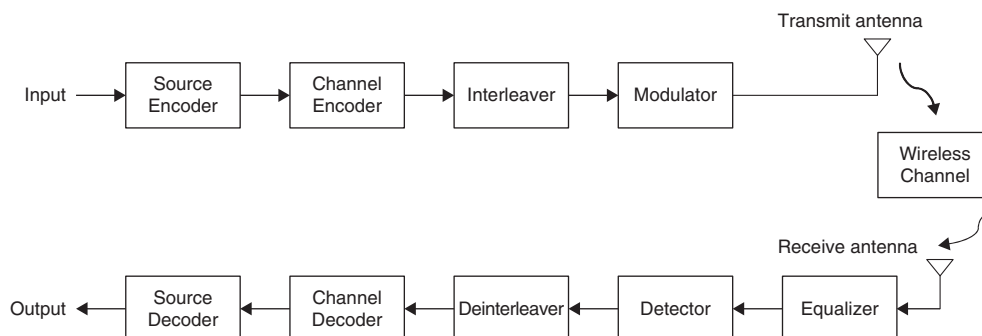

Figure 1: Basic elements of a mobile radio communications system

input signal and represent the signal in an efficient way. Because the channel is unavoidably noisy, the transmit signal becomes corrupted, which leads to error at reception. The purpose of channel encoding is to add redundant bits to the information in a controlled manner in order to reduce reception error. To overcome deep fading of the wireless channel, interleaver is usually added in wireless communications systems to scramble the bits before modulation. The modulator modulates the discrete bits into continuous waveforms that can be sent via a transmit antenna through the wireless channel. On the receiver side, the receive antenna usually receives a distorted signal due to the additive noise and wireless fading channel. To compensate for the distortion of the wireless multipath channel, an equalizer may be employed at the receiver, though multi-carrier modulation has been used instead in many current 3G systems. The detector performs some signal processing techniques on the received distorted signals and makes the decision about transmit signals according to certain predefined decision rules. One example of this is matched filter detector. The rest blocks at the receiver are just the counter blocks of each component at the transmitter. The deinterleaver, performing the inverse function of the interleaver, puts the bits into the original order. The channel decoder removes the redundant bits added by the channel encoder. The source decoder maps the coded bits into the information message.

Mobile radio communications includes a broad range of topics, each of which needs a separate chapter in order to provide detailed discussion. Because a single chapter cannot fully cover it all, we aim to provide an overview of some major components and try to avoid mathematical details as much as possible due to the page limit. The remaining sections of this chapter are organized as follows: “Antennas” discusses the antenna configuration used in mobile radio communications systems today and what is currently evolving. In “Speech Coding,” speech coding is presented with the different options and challenges of speech compression. Next, “Channel Coding” describes channel coding and includes some examples. “Digital Modulation for Fading Channel” and “Equalization” discuss digital modulation for fading channel and equalization. MIMO systems are described in “MIMO Systems.” Lastly, “Conclusion” provides a summative conclusion of the previous sections.

ANTENNAS

The antenna is a device that radiates signal energy over radio frequency (RF) from transmitter to outside and receives RF energy from outside to the receiver (Okamoto, 2002). Because the antenna transfers information through an RF signal, it is crucial for any communications system. The design of antennas has a big influence on spectrum efficiency and quality of services (QoS). Traditionally, there are two major types of antennas, omnidirectional and directional. The omnidirectional antenna radiates or receives energy equally well in all directions, while the directional antenna transmits or receives signal energy in some specific direction. The communication mode can be classified as either half duplex or duplex. In half duplex mode, the transmitter and receiver are generally connected to the same antenna. When a

transmitter transmits, the receiver has to keep silent, and vice versa. The transmission and reception are controlled by an electronic switch, which prevents the transmitter output from damaging the receiver. In half duplex mode, the transmission and reception may or may not be done on the same frequency. In duplex mode, the transmitter and receiver are attached to different antennas, so that transmission and reception happen simultaneously. The two antennas usually operate at two frequencies considerably separated so that the transmission does not interfere with reception.

Antennas for Base Station

In cellular networks, the purpose of a base station is to transfer signals between mobile users and the core network through a radio link in microwave frequency ranging from several hundred MHz to several GHz (e.g., AMPS [Advanced Mobile Phone System] operates at 806 – 902 MHz, and PCS [Personal Communications Service] operates at 1.85 – 1.99 GHz). In general, a base station consists of antenna boxes, an equipment cabinet, and a mast. The equipment cabinet contains a power supply and the actual transmitter cables, which provide the energy and transfer the signal between the antennas. Depending on the coverage area, the antennas may be mounted on a free-standing mast with height between 20 and 35 meters for wide rural areas, on the roof of a building or outer wall for urban or rural populated areas, or on the wall close to the ceiling within a building.

Many types of antennas are being used for base stations, among which two dominant types of antennas are omnidirectional and directional antennas. The omnidirectional antenna radiates or receives energy equally well in all directions, as shown in Figure 2(a). This type of antenna provides the simplest solution for mobile telecommunications systems, although the gain of an omnidirectional antenna is low because most of the radiated energy is wasted and interference is generated in all directions. On the other hand, the directional antenna transmits or receives energy signals in some specific direction, as shown in Figure 2(b). A base station needs to employ multiple directional antennas to provide full coverage. Compared with the omnidirectional antenna, the directional antenna has a higher gain, because it receives signals in only one direction, which reduces the received interference from other mobile users.

The exposure to the radiofrequency radiation from wireless communications, such as antennas, raises health concerns in the public (Health Council of the Netherlands, 2004). Many national and international organizations have instituted safety guidelines for exposure of the public to the RF energy produced by base station antennas. The most widely accepted standards include the Institute of Electrical and Electronics Engineers and American National Standards Institute (ANSI/IEEE), the International Commission on Non-Ionizing Radiation Protection (IC-NIRP), and the National Council on Radiation Protection and Measurements (NCRP). For instance, for base stations that operate in the 1800-2000 MHz range, the ANSI/IEEE exposure standard for the general public is 1.2 mW/cm-sq. For antennas that operate around 900 MHz, the ANSI/

Figure 2: Radiation pattern for (a) omni-directional antenna (b) directional antenna

IEEE exposure standard for the general public is 0.57 mW/cm-sq (Moulder 2005).

Smart Antennas

A smart antenna is an array of antenna elements connected to a digital signal processor, which enables the system to optimize the radiation and reception based on the location of users (Chrysomallis 2000). These antennas can automatically adjust the antenna direction and reception pattern according to the movement of mobile users and the surrounding environment. The use of these antennas can improve the signal quality and dramatically increase the capacity of a wireless link due to array gain, diversity gain, and interference suppression (Ingram 2000).

The two types of smart antennas are switched beam antennas and adaptive array antennas, as shown in Figure 3. Switched beam antenna systems form multiple predetermined beams with heightened sensitivity in particular directions. For a mobile user within the sector, the switched-beam antennas detect the user's signal strength according to some predetermined scanning pattern, then choose one predetermined fixed beam for best reception quality and switch the beam from one to another as the user changes position. On the other hand, the adaptive array antennas use a variety of signal processing algorithms to dynamically locate and track various types of signals to minimize interference and maximize intended signal reception.

Smart antennas have been developed to achieve Space-Division Multiple Access (SDMA) technique in

Figure 3: Smart antenna (a) switched beam antennas, (b) adaptive array antennas

multi-user environments to complement major multiple access schemes, such as Frequency Division Multiple Access (FDMA), Time Division Multiple Access (TDMA) (for details, see "Time Division Multiple Access"), or Code Division Multiple Access (CDMA) (for details, see "Code Division Multiple Access (CDMA)"). SDMA enables multiple users within the same cell but separated by some distance to use the same radio channel such as frequency, time slot, or code. In the smart antenna system, each antenna element can identify each propagation pattern so that multiple users can be differentiated within a certain resolution. With the channel reuse, SDMA can increase the system capacity significantly.

In summary, smart antenna systems can increase signal gain by combining inputs from multiple antennas, reduce the interference by automatically adjusting the radiation and reception pattern to suppress the interference, and significantly increase the system capacity by exploiting SDMA. However, the great challenge for smart antenna implementation is complexity. The complicated signal processing algorithms have to be executed in real time. It is expected that in the near future, advancement in computer technologies will make smart antenna systems possible for commercial communications systems.

SPEECH CODING

With increasing demand for cellular service, service providers are continuously facing the challenge of accommodating more and more users within limited bandwidth. Low bit-rate speech coding, which aims to transmit speech with the high quality but small channel capacity (Rappaport, 2002), provides a solution to this challenge. Speech coding is a technique for audio signal and speech processing, in which speech is compressed into a code for transmission with speech codecs (coder-decoder). The voice for telephone applications is frequency limited between 200 Hz and a little under 4 kHz. For a band-limited speech signal, a sample of the waveform at a particular rate can be extracted and the signal can be reconstructed with those samples. Speech coding is also referred to as lossy coding (Lucent Technologies 2000). The lower the bit rate at which the coder can deliver speech, the more voice users it can support within a given bandwidth. However, there are tradeoffs in speech compression. To deliver low bit rate, complex algorithms need to be used, which lead to higher processing and computation delays. (For more information, see "Speech and Audio Compression.")

Most speech coders can be classified into two categories: waveform coders and source coders. Waveform coders are designed to replicate and reconstruct the original waveform (after quantization) as much as possible. On the other hand, source coders measure certain parameters from the original speech waveform, and send these parameters to the receiver to reconstruct the waveform using those parameters. In general, waveform coders provide excellent speech quality with low complexity and high robustness. Consequently, they produce a moderate to high bit rate of 32 to 64 kbps. Meanwhile, source coders, using highly complex algorithms, produce low bit rates (less than 32kbps) but they are less robust than waveform coders. In addition, the performance of source

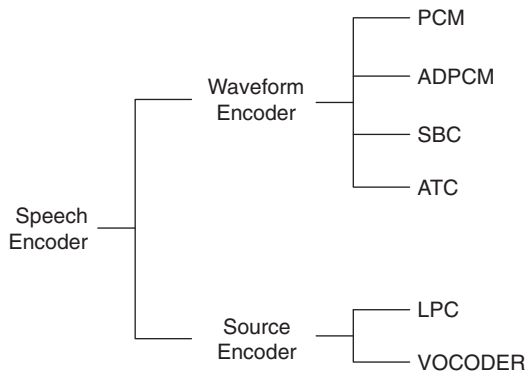

Figure 4: Types of speech coders

coders relies heavily on the speaker. Figure 4 below shows the types of some commonly used speech coders.

Waveform Coders

Pulse Code Modulation (PCM), invented by the British engineer Alec Reeves in 1937 while working for the International Telephone and Telegraph in France, was deployed in the United States Public Switched Telephone Network in 1962 (Hall 1996). A PCM encoder executes three operations on the input signal: filtering, sampling, and quantization. The purpose of the front-end filter is to limit the bandwidth of the input signal so that the signal bandwidth is less than one half of the sampling frequency. A non-uniform quantizer is used to represent the amplitude of each sample as an eight-bit binary codeword. PCM encoder produces an output of a 64 kbps DSO (Digital Signal 0) bit stream corresponding to each voice channel.

Adaptive Differential Pulse Code Modulation (ADPCM) is a differential waveform coder in the time domain, as shown in Figure 5 (Zilog 2005). The speech waveforms are highly correlated; thus, the variances of their differences are very small. Rather than using original quantized and adjacent samples of a speech waveform, the ADPCM coder uses a linear predictor to predict the next sample. The predictor samples are then subtracted from the quantized values of the original speech waveform.

Then the difference is encoded for transmission and sent over the transmission line. This difference between the predicted and actual sample is called the prediction error. Both uniform and non-uniform quantizers can be used in ADPCM coder to quantize values of the original speech waveform (Robinson 2001). The receiver takes a succession of these adjacent sample differences, decodes the samples, and put them together in piecewise fashion in order to reconstruct the original speech waveform. Because encoding the small prediction errors uses less bits, ADPCM can encode speech at a bit rate of 32kbps, which is half the standard 64kbps PCM, while still maintaining the same voice quality as PCM.

Sub-band coding (SBC) is a waveform coding scheme in the frequency domain that works by exploring the statistics of the speech signal. In these coders, speech frequency is divided into a number of sub-bands by a bank of band-pass filters and then the signal in each band is encoded using a different number of bits. For example, in speech, the lower frequency bands contain critical information about pitch and formant; thus more bits are usually allotted in those frequency bands than higher bands in order to preserve the critical information. The design of the filter bank is very important in the SBC design. The filter bandwidth may be equal or unequal. Once the output of each filter is sampled and encoded, the codes are sent over the transmission line. At the receiver side, the receiver has the signals de-multiplexed, decoded, demodulated, and then summed to reconstruct the signal. Sub-band coding can produce the speech coding at bit rates in the range of 9.6 to 32 kbps. In this range, speech quality is roughly equivalent to that of ADPCM at an equivalent bit rate. In addition, its low complexity and relative good speech quality at low bit rates make it particularly advantageous for coding below 16 kbps (Rappaport 2002). SBC has been adopted by the CD-900 cellular telephone system for speech compression.

Adaptive Transform Coding (ATC) is another waveform speech coder in the frequency domain. The ATC transform coder transforms signals into some transform components according to a particular unitary transform and the corresponding inverse-transform is performed at the receiver. Because the unitary transforms tend to

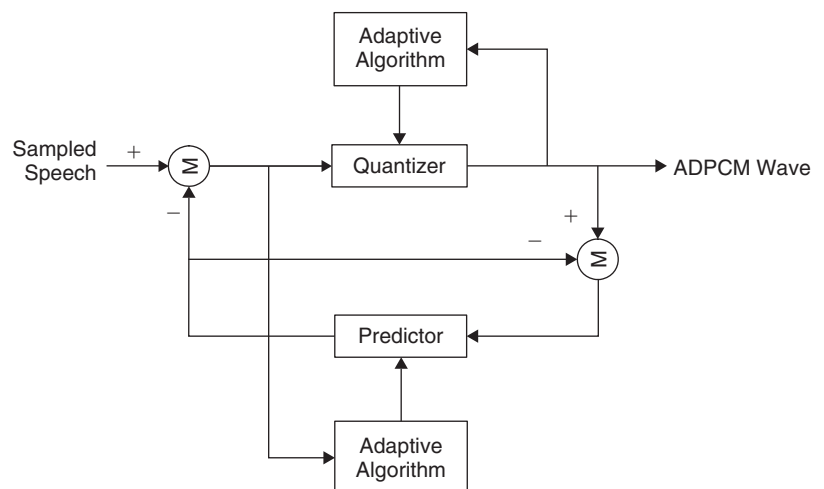

Figure 5: Adaptive differential pulse code modulation encoder

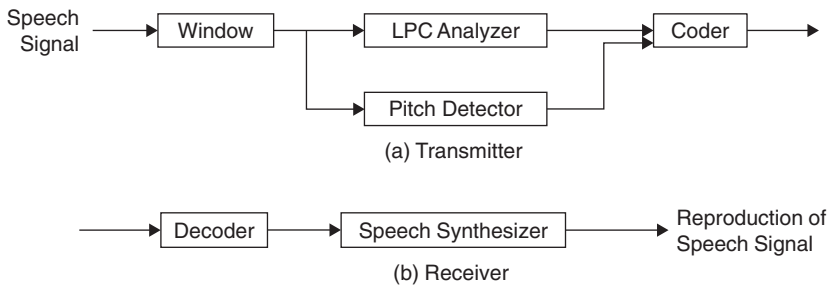

Figure 6: LPC vocoder (a) transmitter, (b) receiver

generate near-uncorrelated transform components that can be coded independently (Spanias 1994), the ATC coder has the potential to reduce the bit rate. In general, ATC can outperform ADPCM by about 6 dB gain at 16 kbps. Although perceptual distortion tends to be small for rates as low as 12 kbps or lower, ATC suffers from the “low-pass filtering” effect, which is a consequence of the fact that only high-energy components are coded (Spanias 1994).

Source Coders

The vocoder (voice coder) is a speech analyzer and synthesizer. Though vocoders were originally developed in 1930s, they were never taken seriously in telecommunications until the late 1970s. Since then, most vocoders have been implemented using linear prediction, whereby the target signal's spectral envelope or formant is estimated by an all-pole IIR (infinite impulse response) filter. In linear prediction coding, the IIR filter is used at the encoder to whiten the signal (i.e., flatten the spectrum) and correspondingly, the decoder at the receiver re-applies the spectral shape of the target speech signal. All vocoder systems attempt to model the generation of the speech process as a dynamic system and try to quantify certain physical limits of the system. Vocoders tend to be much more complex and rigorous than waveform coders, but they can achieve very high economy in terms of the transmission bit rate.

The channel vocoder was the first among the analysis-synthesis systems of speech demonstrated in practice. Channel vocoders are the vocoders in frequency domain that determine the envelope of the speech signal for a number of frequency bands and then sample, encode and multiplex these samples with the encoded output of the other filters. The sampling is done synchronously every 10 to 30 ms. Along with the energy information about each band, the voice/unvoiced decision and the pitch frequency for voiced speech are transmitted.

The formant vocoder is similar to the channel vocoder but theoretically can operate at lower bit rates because fewer control signals are used. Rather than sending samples of the power spectrum envelope, the formant vocoder attempts to transmit the peak positions of the spectral envelope. To represent the speech sounds, a formant vocoder should be able to identify at least three formants. In addition, the intensities of the formants must also be controlled. Formant coders are able to reach bit rates of 12 kbps.

The cepstrum vocoder separates the excitation and vocal tract spectrum by using the Inverse Fourier Transform

of the log magnitude spectrum in order to produce the cepstrum of the signal. The low frequency coefficients in the cepstrum correspond to the vocal tract spectral envelope and the high frequency excitation coefficients form a periodic pulse train at multiples of the sampling period. Linear filtering is performed to separate the vocal tract cepstral coefficients from the excitation coefficients. In the receiver, the vocal tract cepstral coefficients are transformed by Fourier Transform to produce the vocal tract impulse response. By convolving the impulse response with a synthetic excitation signal, the original speech is reconstructed.

Voice excited vocoders are a hybrid that combines the PCM and channel vocoder. Specifically, PCM transmission is used in low-frequency bands of speech and channel vocoding is used in high-frequency bands in order to eliminate the need for pitch extraction of speech waveforms. A pitch signal is generated at the synthesizer by rectifying, band-pass filtering, and clipping the base band signal. This creates a spectrally flat signal with energy at pitch harmonics. Voice excited vocoders have been designed for operation at 7.2 kbps and their quality is usually superior to any general pitch excited vocoder.

Unlike the vocoders, Linear Predictive Coding (LPC) concerns the time domain, as shown in Figure 6 (Zilog 2005). These vocoders strive to extract the significant features of speech from the time waveform. The coefficients of the all pole filter are obtained in the time domain using linear prediction techniques. Specifically, the current sample can be expressed as a linear sum of all the past samples. The predictor coefficients are calculated because the average in the error signal, that represents the difference between the predicted and actual speech amplitude, needs to be minimized. LPCs are similar to ADPCM except that instead of sending differential samples from the transmitter to the receiver, LPCs send selected characteristics of the error signal. These parameters include gain factor, pitch information, and the voiced/unvoiced decision information. Then, the receiver takes the error signal information and uses the error signal itself as the excitation. By using LPCs, it is possible to transmit good quality voice at 4.8 kbps and poorer qualities at even lower rates (Rappaport 2002).

CHANNEL CODING

Data signals transmitted over a channel are inevitably exposed to natural and man-made electromagnetic interferences. The detector at the receiver cannot detect the signal correctly when the received signal is severely distorted.

The situation get worse in wireless radio communications. The wireless channel is random and time-varying; thus, it is more prone to errors. When a wireless channel experiences deep fading, bursts of data bits may be lost. Therefore, data signals must be protected to reduce the errors. Channel coding is a technique to control errors through adding redundancy in a controlled manner. The code rate is defined as the number of message bits over the number of total encoded bits. Channel coding may have either error-detection capability or error-correction capability. Error-detection channel codes can detect transmission errors. Once an error is detected, the receiver sends a request to the transmitter for retransmission. On the other hand, error-correction channel codes have the capability of correcting a certain amount of errors without retransmission. Adding more redundant bits leads to a lower code rate, but in general can increase the error correction capability. If more errors can be corrected, the communications system can operate with a lower transmitted power, can transmit over larger distances, can tolerate more interference, and can use smaller antennas and transmit at higher data rate. However, the cost of low code rates is large bandwidth consumption.

In 1948, Claude Shannon commenced error control coding with his famous publication “A Mathematical Theory of Information” (Shannon 1948). Shannon showed that it was possible to design a communications system with any small probability of error desired whenever the rate of transmission is smaller than the capacity of the channel. In 1950, the first single-error-correcting codes were introduced. In the late 1950s and 1960s, Reed-Solomon Codes and Convolutional codes appeared. Since then, many channel coding techniques have been developed. In this section, three techniques which are widely used in cellular networks are discussed: cyclic codes, convolutional codes, and turbo codes. In addition, interleaving is discussed as a technique to overcome the deep fading in wireless radio communications.

Cyclic Codes

A cyclic code exhibits two fundamental properties, linearity and cyclic properties. A cyclic code is a linear code; that is, the sum of any two code words is also a code word. In addition, any cyclic shift of a code word is also a code word. Cyclic code is usually generated by using a generator polynomial $g(D)$ of degree $(n - k)$ in a (n, k) block, where k is the number of information bits in a block, n is the number of bits in a code word, and $(n - k)$ bits are the redundant parity bits introduced for error control. For instance, the Global System for Mobile Communications (GSM) uses a $(53, 50)$ cyclic code where a block of 50 information bits is coded into a codeword of 53 code bits by adding 3 parity bits (Grech 1999) (for details, see “Global System for Mobile Communications (GSM)”). Encoding for a cyclic code is usually performed by a linear feedback shift register based on either the generator or parity polynomial. For a cyclic code only capable of error detection, the detector at the receiver divides the received discrete data by the chosen parity-check polynomial. If the remainder of the division is not zero, this indicates that an error has occurred and the data block is discarded.

On the other hand, if the remainder is not zero, this indicates that the transmission is error-free. For a cyclic code capable of error correction, syndrome decoding technique can be used for detection.

The popularity of cyclic codes is mainly due to their efficient error-detection capability. As an example, Cyclic Redundancy Check (CRC) codes (Lin and Costello 1983) are cyclic codes typically used in automatic repeat request (ARQ) systems for error detection (Lin, Costello, and Miller 1984). Though some cyclic codes have no error-correction capability, they can be combined with another error-correcting code to improve performance. For example, GSM uses the combination of cyclic codes and convolutional codes for channel coding.

Convolutional Codes

In contrast to block codes, in which information bits are grouped into blocks and codewords are generated on a block-by-block basis, convolutional codes encode the incoming message sequence continuously in a serial manner (Pless 1998). A convolutional code consists of a K -stage shift register and n additional operators. Each stage in the shift register holds k bits. The information bits pass through the shift register k bits at a time. Each additional operator takes the bits from the shift register to generate an output bit. Therefore, k -bit input is encoded into n -bit output and the rate of the code is $R=k/n$. Figure 7 shows the block diagram for the convolutional coder, where the shift register has $K = 5$ stages, each stage holds $k = 1$ bit, and the number of additional operator is $n = 2$. Thus, $R = 1/2$ is the code rate; that is, the output bit rate is twice the input rate. Each output bit depends on the state of the registers and on the actual input, providing a kind of prediction capability to the detector in order to determine incorrect transitions on the received coded data.

If no errors occur, the received message can easily be related back to the original bit stream, given the initial condition. With the aid of the Trellis diagram (Proakis 2001), a received message can be decoded according to maximum likelihood method when the received data contains errors. However, maximum likelihood decoding

Figure 7: Convolutional encoder

results in a high load of computation work. Thus, some systematic procedure is required to reduce the computation complexity, especially when the error location of the frame is unknown or when more than one error occurs. One widely used algorithm is the Viterbi algorithm (Viterbi 1967; Forney 1973). Exploring the structure of the path metric computation, the Viterbi algorithm only considers the paths that can reach the highest path metric and discards the rest. Both computation and required memory are reduced significantly, compared to the maximum-likelihood decoding.

Convolutional codes provide error tolerance and error correction capability. In addition, they permit a transmitter to transmit with low power. Convolutional codes have been adopted in both GSM and IS-95 systems for error control. In many applications where the noise is predominantly Gaussian, the better solution is obtained when block and convolutional codes are jointly used in series. To improve performance in wireless fading channel, convolutional codes are commonly used with interleaving (a detailed discussion of interleaving is provided later in the chapter). This type of interleaver, usually referred as a *convolutional interleaver*, is designed both to smear the error bursts and to work well with the incremental nature of convolutional code generation (Forney 1971).

Turbo Codes

Turbo codes are a class of powerful error correction codes that were introduced in 1993 by a group of researchers from France: Berrou, Glavieux, and Thitimajshima, along with a practical decoding algorithm (Berrou et al. 1993). Turbo codes have large coding gains and allow a wireless communications link to come amazingly close to the theoretical limit specified by Shannon Capacity Theorem. In order to achieve low-power performance, the turbo encoder deals with large-size blocks of message bits. Because of the long latency involved in such large block codes, turbo codes did not gain much attention at the beginning. With the use of widespread spectrum in 3G cellular networks, turbo codes became applicable and started to gain a lot of attentions. Turbo codes have been used for low-power applications such as deep-space and satellite communications, as well as for interference-limited applications such as PCS systems. In addition, turbo codes have been adopted by Wideband CDMA (WCDMA) interface for third-generation cellular systems.

The basic block diagram for a turbo code encoder is shown in Figure 8. A turbo code encoder consists of two (or more) systematic recursive convolutional encoders separated by an interleaver that performs a scrambling

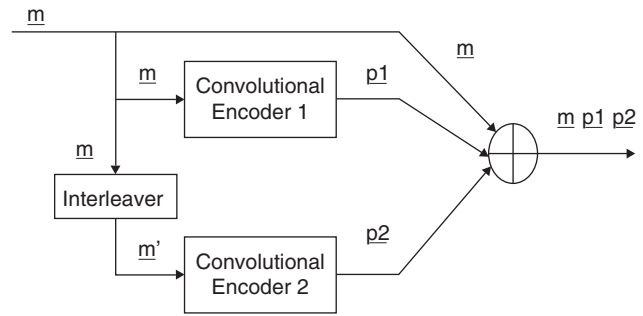

Figure 8: Turbo encoder

operation on the input message sequence. The two convolutional encoders generate two different sets of parity bits, p_1 and p_2 . Using two encoders can achieve considerable coding gains in spite of the iterative soft decoding schemes whose complexity is only twice of a single convolutional decoder.

The complete encoded sequence is formed by three sub-blocks. The first one is the sequence itself, that is, the k -bit input sequence m . The second sub-block is the encoder 1 output, which corresponds to $n/2$ parity bits obtained from the sequence passed to a convolutional encoder. The third sequence is another $n/2$ parity bits obtained from passing a pseudo randomly interleaved copy of m to a second convolutional coder. Therefore, the encoded output sequence has $N = n/2 + n/2 + k = (n+k)$ bits. Then the code rate is the k -bit input over the N output bits, i.e.,

$$R = \frac{k}{k+n}.$$

The iterative decoding algorithm is based on simple decoders individually matched to the simple constituent codes. Each constituent decoder sends an estimated posteriori likelihood of the decoded bits to the other decoder, and uses the corresponding estimates from the other decoder as a priori likelihood. The received bits, corrupted by the noisy channel, are available to each decoder to initialize the a priori likelihoods. The decoders may use the soft output Viterbi Algorithm (SOVA) or a Maximum a-Posteriori decoding algorithm (MAP). The turbo decoder iterates between the outputs of the constituent decoders until reaching satisfactory convergence. The final output is a hard quantized version of the likelihood estimates of either of the decoders. The decoder block diagram is shown in Figure 9. The dotted lines show the iterative path. Note that the turbo decoding algorithms may not converge and in general six iterations can provide satisfactory performance.

Figure 9: Turbo decoder block diagram

Though turbo codes allow a communications link to closely approach closely the Shannon limit, they exhibit an error floor phenomenon (Perez, Seghers, and Costello 1996), which results in a relatively high bit-error rate (BER). One solution to the problem is concatenating turbo codes with another type of code. Low-Density Parity-Check codes (LDPC) are a good choice. LDPC codes were originally invented by Gallager (Gallager 1962), and then revisited by Mackey (Mackay and Neal 1996). LDPC codes are linear block codes with a low-density parity check matrix. They can come near to the Shannon limit with relatively low decoding complexity. The concatenated LDPC-turbo code, which uses LDPC code as an outer code and turbo code as an inner code, can achieve very low BER and improve the performance of turbo codes (Kou, Lin, and Fossorier 2001).

Interleaving

Though many channel codes have the error-correction capability, the number of errors within a single codeword that can be corrected is limited. In another word, channel codes usually cannot correct burst of errors. When a wireless channel exhibits deep fading for a certain time period, all the bits transmitted during this period may get lost, and in general, those errors cannot be corrected. Interleaving is a technique in combination with channel coding to improve performance in a fading channel. The main function of interleaving is to spread out bursts of error bits in time over multiple codewords so that if a deep fade or noise burst occurs, the errors can still be corrected by channel codes. In the spatial analogy, the interleaver pushes the points farther apart in space, which decreases the probability of error. In turbo code encoder, the interleaver scrambles bits in a pseudo random predetermined fashion to bring more diversity to the codewords.

A variety of interleaving approaches is possible. Conceptually, the simplest approach is block interleaving, in which the interleaver memory is viewed as a rectangular array of storage locations. Block codes are usually combined with block interleavers so that the error bursts can be spread out across multiple codewords. For convolutional codes, in which the notion of codeword does not exist, the convolutional interleavers are designed in a slightly different way. A block interleaver is used to illustrate the general operations. The block interleaver operation is shown in Figure 10 (a). The data are written in memory by columns. When the memory array is full, the stored data are read out by rows. Block deinterleavers perform the inverse operation by writing the received data into the rows of a similar memory array and reading them out by columns after the array is full, as shown in Figure 10 (b). The size of the interleaver depends on the fading characteristics of wireless channel. Slow fading channel in general needs large interleavers so that all the bits in a received codeword are rather independent.

Though interleaving can improve the performance in terms of probability of error, especially in deep fading channel, it introduces additional delays. In block interleaving, the read-out operation for both interleaver and deinterleaver can only be performed when the memory array is full. Interleavers of large size generate large delays.

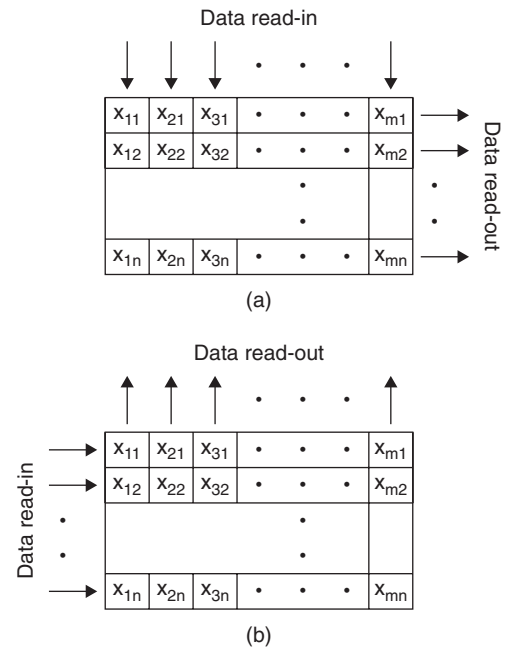

Figure 10: (a) Block interleaver, (b) block deinterleaver

Moreover, interleaving basically removes the correlation of fading, which information may be used for optimum maximum likelihood decoding. Therefore, coding combined with interleaving may cause a decrease in the channel capacity (Goldsmith and Varaiya 1996).

DIGITAL MODULATION FOR FADING CHANNEL

Modulation is a process of conveying information through electronic signals. In general, the information or message-bearing signals are superimposed upon a carrier signal for transmission. Sinusoidal signal is the typical carrier signal. Because various modulation techniques are discussed in detail in Part 2 of Volume I, this section provides a general overview of various modulation schemes, followed by detailed discussions of adaptive modulation.

Overview of Modulation Schemes

Modulation can be classified as analog modulation and digital modulation. In analog modulation, a carrier signal is varied continuously in phase, frequency, or amplitude. Analog modulation includes Phase Modulation (PM), and Frequency Modulation (FM) (for more details, see "Frequency and Phase Modulation"), and Amplitude Modulation (AM) (for more details, see "Pulse Amplitude Modulation"). PM is not widely used, because it tends to require more complex receiving hardware and there can be ambiguity problems in detection. FM is commonly used at VHF radio frequencies for high-fidelity broad casts of music and speech. AM is commonly used at radio frequencies.

Over the years a major transition has occurred from analog modulation to digital modulation, which converts

an information-bearing discrete-time symbol sequence into continuous waveform. Digital modulation mainly includes Amplitude Shift Key (ASK), Frequency Shift Key (FSK), and Phase Shift Key (PSK) (for more details, see, “Digital Phase Modulation and Demodulation”). ASK changes the amplitude of a carrier wave to represent digital data. This technique is used in optical fiber communications. FSK shifts the output frequency to achieve distinct waveforms. FSK may be used for high-frequency radio communications or used in Local Area Networks (LAN) that use coaxial cable as media. PSK is a digital modulation scheme that conveys data by changing or modulating the phase of a sinusoidal signal. Examples of PSK modulation techniques include BPSK, QPSK, Offset QPSK, $\Pi/4$ -QPSK, and DPSK. Because symbol signals are distinct by their phases, phase needs to be aligned between transmitter and receiver so that the detector can perform the decision making. In addition, hybrid modulation techniques have also been developed, such as Quadrature Amplitude Modulation (QAM) that varies both phase and amplitude. QAM can represent multiple bits per symbol, and can thus deliver high data rate. QAM and its derivatives are used in both mobile radio and satellite communication systems.

In general, PSK and FSK are considered to be lower order modulation techniques, because each distinct signal represents fewer bits. Therefore, the system capacity is low. On the other hand, 16QAM, 64QAM, etc., are referred to as higher order modulation techniques, because each signal represents more bits. High data rate can be achieved by applying higher order modulation techniques. However, applying higher order modulation requires good channel condition in order to maintain certain bit error rate performance. The choice of modulation scheme depends on various factors, such as spectral efficiency, BER performance, power efficiency, cost and ease of implementation, channel condition (e.g., carrier-to-interference ratio), robustness to the multipath effect, etc. Some applications of digital modulation techniques are given in Table 1 (Fitton 2003).

In traditional communications systems, the radio transmission method is designed to cope with channel variations in a worst-case manner. For wireless systems, this implies the use of a simple modulation scheme, and

a complex error-correcting code. When the coding fails to compensate for temporary bad conditions, higher layers in the protocol ensure that the information is correctly and completely transmitted by requiring a retransmission of the erroneous data. Though simple, the traditional modulation setup is inefficient as it is designed for the worse-case scenario and cannot adapt to the time-varying channel condition.

Adaptive Modulation

Adaptive modulation, or link adaptation, is a powerful technique for improving the spectral efficiency in wireless transmissions over fading channels. The idea is to make efficient use of the bits: Whenever the channel conditions are adequate, transmission of redundant bits should be avoided (Ericsson 1999). To also achieve a high throughput over fading channels, the modulation parameters—such as signal constellation size, transmitted power level, and data rate—should be adjusted according to the channel conditions. The adaptation can also take into account requirements of different traffic classes and services such as required bit error rates. (Falahati et al. 2002).

Higher order modulations allow users to send more bits per symbol and thus achieve higher throughputs. However, higher order modulations require higher signal-to-noise ratios (SNRs) to overcome any interference and maintain a certain BER. The use of adaptive modulation allows a wireless system to choose the highest order modulation depending on the channel conditions. When the channel condition is good (e.g., mobile is close to the transmitter), the user receives higher SNR and thus can utilize higher order modulations like 64-QAM to increase throughput. As the mobile moves away from the transmitter (i.e., the channel is getting bad), the received SNR is decreased and the user has to step down to lower modulations (e.g., BPSK) in order to maintain certain BER. In addition, adaptive modulation allows the system to overcome fading and other interference.

Adaptive modulation is sensitive to measurement error and delay. To select appropriate modulation, the system must be aware of the channel quality. Errors in the channel estimate cause wrong modulation selection. It is well known that turbo codes are specified as the channel coding technique for packet data in the 3G standards. Even a small prediction error in channel SNR can result in a large degradation in BER. Therefore, it is essential to take into account the possible prediction errors when designing an adaptive modulation system where turbo codes are employed (Yang et al. 2002). Delay of channel measurement also reduces the reliability of channel quality estimate. Furthermore, changes in the interference add to the measurement errors.

Conventionally, the threshold method is used to determine which modulation scheme should be used in adaptive modulation. The threshold values for the average channel SNR values are denoted by $[-\infty, \gamma_1, \dots, \gamma_{n-1}, \infty]$. These threshold points partition the range of SNR into n regions, denoted by $[\gamma_i, \gamma_{i+1})$ for $i = 0 \dots n-1$. One modulation scheme is assigned for each SNR region. One example is shown in Table 2 (IEEE Standard 802.16 Working Group 2004).

Table 1: Modulation Schemes for Various Applications

Modulation Format	Application
BPSK	Deep space telemetry, cable modems
QPSK	Satellite, CDMA, DVB-S, cable modems
OQPSK	CDMA, stellite
MSK, GMSK	CDPD, GSM
FSK, GFSK	DECT, paging, AMPS, CT2
8PSK	Satellite, aircraft
16 QAM	Microwave digital radio, modems
32 QAM	Terrestrial microwave, DVB-T

Table 2: Adaptive Modulation for 802.16d

Modulation	BPSK	QPSK	16 QAM	64 QAM
SNR threshold (dB)	6.2 – 8.2	9.4 – 11.2	16.4 – 18.2	22.7 – 24.4

Table 3: Modulation and Coding Schemes for IEEE 802.16d

Rate ID	Modulation rate	Coding	Information bits/symbol	Information bits/ OFDM symbol	Peak data rate in 5Mhz (Mbps)
0	BPSK	1/2	0.5	88	1.89
1	QPSK	1/2	1	84	3.95
2	QPSK	3/4	1.5	280	6.00
3	16 QAM	1/2	2	376	8.06
4	16 QAM	3/4	3	568	12.18
5	64 QAM	2/3	4	760	16.30
6	64 QAM	3/4	4.5	854	18.36

The first version of IEEE standard 802.16, completed in October 2001, defines the air interface and medium access control (MAC) protocol for a wireless metropolitan area network (WMAN™), intended for providing high-bandwidth wireless voice and data for residential and enterprise use. This is the first industry-wide standard that can be used for fixed wireless access with substantially higher bandwidth than most cellular networks. The IEEE 802.16 standard, often referred to as WiMax, heralds the entry of broadband wireless access as a major new tool in the effort to link homes and businesses to core telecommunications networks worldwide. Adaptive Modulation and Coding (AMC) is adopted by IEEE 802.16 standard. Specifically, the 802.16a/d standard defines seven combinations of modulation and coding rate that can be used to achieve various trade-offs of data rate and robustness, depending on channel and interference conditions. These possible combinations, shown in Table 3, follow a pattern similar to the modulation/coding pairs available in the IEEE 802.11 a/g standard for wireless LANs (IEEE Standard 802.16 Working Group, 2004).

The allowed modulation schemes in the downlink (DL) and uplink (UL) are BPSK, QPSK, 16-QAM, and 64-QAM. A total of eight pilot sub-carriers are inserted into each data burst in order to constitute the OFDM symbol, and they are modulated according to their carrier locations within the OFDM symbol. Additionally, known preambles are used in 802.16d to aid the receiver with synchronization and channel estimation. In the DL, a “long preamble” of two OFDM symbols is sent at the first 184 bits of each frame. In the UL, a “short preamble” of one OFDM symbol is sent by the SS at the beginning of every frame.

EQUALIZATION

Time dispersion in radio channel due to multipath propagation may cause Inter-Symbol Interference (ISI), in

which a given transmit signal is distorted by other transmit symbols, causing bit errors at the receiver (for details see “Wireless Channels” and “Cellular Communications Channels”). ISI is one of the major obstacles to high speed data transmission over wireless channels. Generally speaking, equalization refers to any signal processing technique used at the receiver to reduce the ISI. Signal processing techniques can also be employed at the transmitter to combat the delay spread, such as spread spectrum. (For details, see “Spread Spectrum”) and multicarrier modulation. This section focuses on equalization only.

Introduction to Equalization

The concept of equalization is shown in the frequency domain in Figure 11. Suppose the channel does not have equal gain over the spectrum due to multipath propagation. Equalizer is designed to have frequency response equal to the inverse of channel frequency response. In this way, the combined filters provide a unity gain over the complete spectrum. In the time domain, this means that convolution of the channel impulse response and the equalizer impulse response is equal to one at the center tap and has nulls at the other sample points within the filter span. Equalization techniques are classified into two categories: linear and nonlinear. Some examples of equalizers are described later in this section.

Because the radio fading channel is random and time-varying, an equalizer should be adaptive so that it can track the time of varying characteristics of the mobile channel and self-adjust to the unknown environment to provide reliable performance (Rappaport 2002). In other words, adaptive equalization does not require any prior information about the channel and the transmitted data. An array of adaptive equalizers can also be used in flat fading applications to perform diverse combinations to enhance signal level. The general operations of

Figure 11: Equalized channel

an adaptive equalizer include training and tracking. First, a known, fixed-length training sequence is sent by the transmitter so that the receiver's equalizer may adapt to a proper setting for minimum BER detection. The training sequence is typically a pseudorandom binary signal or a fixed, prescribed bit pattern. Immediately following this training sequence, the data is sent, and the adaptive equalizer at the receiver uses a recursive algorithm to evaluate the channel and estimate filter coefficients in order to compensate for the distortion created by multipath in the channel (Rappaport 2002).

Linear Equalization

Linear equalizers typically compare a received time-domain reference signal to a stored copy of the undistorted training signal. With a comparison of the two, a time-domain error signal is determined that may be used to calculate the coefficient of an inverse filter. The formulation of this inverse filter may be accomplished strictly in the time domain (e.g., zero-forcing equalization and least mean square equalization), or converted in spectral representation. A spectral inverse response can be calculated to compensate for the channel response. This inverse spectrum is then converted back to a time-domain representation so that filter tap weights may be extracted.

The zero-forcing equalization (ZFE) technique is a simple method to form an inverse filter. To formulate a set of FIR inverse filter coefficients, a training signal consisting of an impulse is transmitted over the channel. By solving N simultaneous equations based on the received sample values, a set of coefficients can be determined to force all but the center tap of the filtered response to zero. This means, the $(N - 1)$ samples surrounding the center tap do not contribute ISI. The main advantage of this technique is that the solution to the set of equations is reduced to a matrix inversion. The major drawback of ZFE is that the channel response may often exhibit attenuation at high frequencies around one-half the sampling rate (the folding frequency). Because the ZFE is simply an inverse filter, it applies high gain to these upper frequencies, which tends to exaggerate noise. A second problem is that the training signal, an impulse, is a low-energy signal, which results in a much lower received signal-to-noise ratio than could be provided by other training signal types (Qureshi 1992).

The least mean squared (LMS) equalizer is a more general approach (Proakis 2001). In contrast to the ZFE that solves a set of N simultaneous equations, LMS iteratively adjusts the coefficients during each sample period in the training sequence and eventually converges to a set of optimal coefficients. These coefficients minimize

the error between the equalized signal and the reference signal stored in the equalizer. Only one parameter, the adaptation size, needs to be adjusted. There is a tradeoff in the choice of step size between speed of convergence and residual steady-state error. If step size is set too large, the filter converges rapidly but stops at some coefficients around the optimal ones with some error. It is shown that the LMS equalizer has better noise performance than the ZFE. Another major advantage of LMS equalizer is that any arbitrary sequence can serve as a training sequence. In general, it is desirable to use a high-energy signal to improve the received signal-to-noise ratio of the training sequence. Typical training sequences employed for LMS equalization include pseudorandom noise sequences and chirp-type signals.

Nonlinear Equalization

On the other hand, nonlinear equalizers attempt to minimize an error signal based on the difference between the output of the equalizer and the *estimate* of the transmitted signal, which is generated by a decision device. In other words, the equalizer filter outputs a sample and the predictor or decision device determines what value is most likely transmitted. The adaptation logic endeavors to keep the difference small between the two. The main idea is that the receiver takes advantage of the knowledge of the discrete levels possible in the transmitted pulses. When the decision device quantizes the equalizer output, it is essentially throwing away received noise. Typically, training is used to make a filter converge at startup as part of the initialization overhead. Adaptation techniques can then be employed to track and compensate for minor variations in channel response on the fly using the detected version of its output signal. This equalization is called the decision-directed equalization, as shown in Figure 12. When the adapted filter is perfect, the filter produces the actual transmit symbol value and the error of the decision device would be zero. In practice, the error can never be zero. However, if the adapted filter is near perfect, the predictor is able to remove significant received noise, leading to perfect decisions. The coefficient update can be performed similar to that for the LMS equalizer.

Decision-feedback equalization (DFE) is another nonlinear adaptive equalizer, in which a feedback filter structure is used to achieve the post-cursor ISI removal. When the decision device makes a decision on the current symbol, the decided sequence is then fed back through a feedback filter to calculate the ISI by subtracting the decided symbol value from the received signal (Svensson 1989). Because the same amount of ISI tends to occur

Figure 12: Decision-directed equalization

in subsequent transmission, the current ISI value is used to compensate the input to the decision device for the next symbol detection. DFE is the most common nonlinear equalizer due to its simple implementation and fairly good performance. However, when channels are noisy, DFE tends to propagate errors and consequently causes performance degradation.

MIMO SYSTEMS

Multiple-input-multiple-output (MIMO) communications systems refer to the systems that use multiple antennas at both the transmitter and the receiver. By deploying multiple antennas, MIMO systems establish many multi-path fading paths between each transmit and receive antenna pair. In high scattering environments, these multiple fading paths can be assumed independent. When the multiple transmit antennas transmit the same symbol simultaneously, MIMO systems create spatial diversity and consequently improve performance in terms of probability of error. On the other hand, when each transmit antenna transmits an independent symbol, MIMO systems achieve significant capacity gains through multiplexing.

A spatial multiplexing MIMO system with N transmit antennas and M receive antennas is shown in Figure 13. The transmit antennas transmit independent data on different transmit antennas simultaneously in multiplexing. Let x denote the independent transmit signals at the transmitter, y denote the received signals at the receiver, and H denote the channel matrix. The received signal can be expressed as,

$$y = Hx + n$$

where n is the noise. Channel matrix H is a $M \times N$ matrix,

$$H = \begin{bmatrix} h_{11} & h_{12} & h_{13} & \cdots & h_{1N} \\ h_{21} & h_{22} & h_{23} & \cdots & h_{2N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ h_{M1} & h_{M2} & h_{M3} & \cdots & h_{MN} \end{bmatrix}$$

When the channel is wireless fading channel, the gains h_{ij} are random.

For wireless fading channel, the capacity of multiplexing MIMO systems depends on whether or not the transmitter and/or receiver know the channel matrix. When both the transmitter and receiver know the channel matrix perfectly, the transmitter can adaptively adjust power allocation according to channel fading. When the power allocation is optimized, the capacity equals the average channel matrix realization. However, most commonly the channel matrix is known only by the receiver and the transmitter is not aware of the channel fading. In this case, the transmitter can only decide a transmission strategy based on the distribution of channel matrix H , and the channel capacity can be formulated as

$$C = \log_2[\det(I_M + \frac{\rho}{N} HH^H)]$$

where ρ is the average signal-to-noise-ratio per transmit antenna, and I_M is an identical $M \times M$ matrix. It is shown that the capacity grows linearly with $\min(M, N)$ rather than logarithmically (Foschini and Gans 1995; Telatar 1995).

To reduce the decoding complexity, a linear receiver can be employed at the front ends to separate the transmitted data streams and then independently decode each stream. Examples of linear receivers include the zero-forcing receiver and minimum-mean square error receiver. Some nonlinear receivers may also be used, such as the maximum likelihood receiver and successive interference cancellation receiver. MIMO systems employ various space-time coding schemes to offer a significant diversity advantage over traditional wireless communications systems (Gesbert et al. 2003). The space-time codes (STC) are designed to explore both the space domain (over multiple antennas) and the time domain (over multiple time slots). Some STCs, such as Space-Time Block codes, can only provide the diversity gains, while some STCs, such as Space-Time Trellis codes, can provide not only diversity

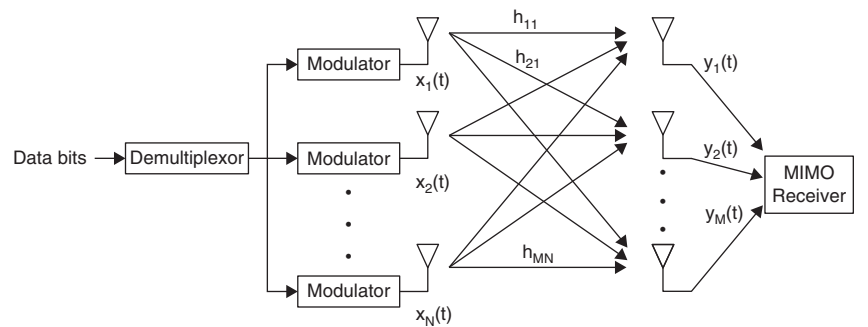

Figure 13: MIMO spatial multiplexing systems

gain but also coding gain. These benefits have made MIMO technology promising for next-generation communications systems.

MIMO systems deliver greater performance, but with additional cost of deploying multiple antennas and additional power consumption to operate those antennas and perform multidimensional signal processing. Competition of consumer markets imposes pressure on the cost, while limited battery life constrains the tolerable power consumption in wireless portable devices. One low-cost solution is the high system-level integration of CPUs and other peripherals (Diouris 2005). To achieve highest performance, the antennas need to be placed far apart, yet small user devices like cell phones requires antennas to be close to each other. One way to solve this problem is to employ antennas with different polarization and radiation patterns for minimal overlapping.

CONCLUSION

This chapter examines major components of mobile radio communications, including antennas, speech coding, channel coding, digital modulation, equalization, and MIMO systems. Antennas are crucial for any communications system. The most common are the omni-directional antenna and directional antenna. The smart antenna, one type of directional antenna, has emerged as a promising antenna technique. Speech coding is an audio signal and speech processing technique in which speech is compressed into a code for transmission. Two major categories of speech codes are discussed: waveform coders and source coders.

In mobile radio communications, transmitted data signals are exposed to natural and man-made electromagnetic interferences. Channel coding aims to control these errors by adding redundancy. Three widely used channel codes are presented: cyclic codes, convolutional codes, and turbo codes. In addition, the interleaving technique is introduced. Its function is to spread out successive bits produced from speech coders, so that the lost bits due to deep fading can be recovered through channel coding.

Modulation techniques, also discussed in this chapter, are a process of representing information by varying carrier signals. In this chapter, the focus is on the adaptive modulation technique specifically for mobile radio communications, although modulation techniques are covered in other chapters in this book. Equalization is used to compensate for the distorted wireless channel so that the bit error rate is reduced. Lastly, MIMO systems are discussed. By employing multiple antennas at both the transmitter and receiver, MIMO systems can either increase system capacity through multiplexing or improve performance through diversity.

Because the broad range of topics in mobile radio communications cannot be covered in a single chapter, we only provide an overview of some major components. Though some omissions are unavoidable, fortunately other chapters in this book, especially in Part 3 of Volume II provide complementary discussions. For instance, specific cellular networks are discussed in "Global System for Mobile Communication (GSM)," "General Packet Radio Service (GPRS)," "Universal

Mobile Telecommunication System (UMTS)," and "IMT-2000 (International Mobile Telecommunications-2000) and 3G Wireless Systems." (Please refer to the table of contents for complete coverage). As the communications systems move to the next generation, which will require high speed and ubiquitous access, new technologies will be developed to provide various applications with different QoS supports.

GLOSSARY

Antenna: A device that radiates signal energy over radio frequency from transmitter to outside and receives radio frequency energy from outside to the receiver.

Channel coding: A technique to control errors by adding redundancy bits in a controlled manner.

Equalization: Signal processing technique used at the receiver to reduce the Inter-Symbol Interference.

Interleaving: A technique used to spread out bursts of error bits to improve performance in a fading channel.

Mobile radio communications: Transferring information through the electromagnetic signal over wireless radio channel between mobile users.

Modulation: A process of conveying information through electronic signals.

Multiple-input-multiple-output (MIMO) systems: Systems that use multiple antennas at both the transmitter and the receiver.

Smart antenna: An array of antenna elements connected to a digital signal processor which enables the system to optimize the radiation and reception based on the location of users.

Speech coding: An audio signal processing and speech processing technique in which the speech is compressed into a code for transmission.

INTRODUCTION

The use of cellular telephony has expanded dramatically worldwide within the past two decades. According to an International Telecommunications Union (ITU; n.d.) report, the number of mobile phones worldwide has outnumbered fixed-line phones. Several technical innovations have contributed to the success of mobile phones. In particular, cellular telephony systems can now be deployed much more economically; the handsets have become smaller and lighter, battery life has increased, digital technology has improved reception, and the costs associated with mobile telephones have been decreasing. In addition, newer generation devices, with access to the Internet and built-in digital cameras, are becoming the mainstream in many countries in Europe and Asia. New types of wireless services, such as Web access, instant messaging, e-mail, and location-dependent services, have helped to further increase the popularity of mobile phones.

In the history of cellular network evolution, the first thirty years of cellular telephony saw little market penetration due to high cost and the technological challenges involved (Rappaport 2002). The forerunner of cellular network was police radio systems. By 1934, fifty-eight state police stations had adopted amplitude modulation (AM) mobile communication systems for public safety in the United States, serving more than 5,000 radio-equipped police cars (Rappaport 2002). The theory and techniques of cellular telephony were developed by AT&T Bell Laboratories and other telecommunication companies during the 1950s and 1960s. In 1968, AT&T proposed the concept of cellular telephony to the Federal Communications Commission (FCC). The proposed cellular concept divides the service area into many small regions known as cells, each served by a low-power transmitter with moderate antenna height known as a base station (BS). Frequency channels

are assigned for data transmission between a BS and mobile phones inside the radio coverage area of the BS. Frequency channels are not reused in adjacent cells to avoid interference. Cells using different frequency channels form a cell cluster. Channels are only reused in different clusters and when there is sufficient distance between the transmitters (MacDonald 1979).

The technology to implement the concept of cellular telephony was not available until the late 1970s. In 1979, Nippon Telephone & Telegraph (NT&T) introduced the first cellular system in Japan (Agrawal and Zeng 2003; Chandran and Valenti 2001). The microprocessing technology revolution in the 1980s helped to easily implement wireless communication protocols, and the digital control link between mobile telephones and the BS helped to realize the cellular concept. In 1983, the advanced mobile phone system (AMPS) was deployed in Chicago, Illinois. AMPS was the first U.S. cellular telephone system and relied on frequency division multiple access (FDMA) to maximize system capacity.

In Europe, several first-generation cellular systems were introduced in different countries. The Nordic mobile telephone (NMT) system was first developed in 1981 and operated in the 450 MHz frequency band. The European total access cellular system (ETACS) was deployed in 1985 and was virtually identical to the U.S. AMPS system. In the same year, the C-450 cellular standard was introduced in Germany. These cellular systems were not compatible with each other because of the different frequencies and communication protocols used. In addition, the digital transmission technique had become more mature and economical. In 1990, the pan-European digital cellular standard, Group Special Mobile (GSM), which uses the digital transmission technique to transmit digital signals, was deployed to replace those incompatible first-generation

cellular systems. Group Special Mobile was founded in 1982 by the Conference of European Posts and Telegraphs. Later, the European Telecommunications Standards Institute (ETSI) assigned new meanings to the standard GSM letters, resulting in today's global system for mobile communications. The GSM system supports roaming in Europe and is currently accepted worldwide in more than 210 countries.

In the United States, the AMPS system was gradually replaced by the U.S. digital cellular (USDC) system, a second-generation cellular system, in the 1990s. The USDC standard (Electronic Industry Association Interim Standard IS-54 and, later, IS-136) uses time division multiple access (TDMA) together with FDMA and increases the system capacity threefold. In 1993, a new cellular system based on code division multiple access (CDMA) was proposed by Qualcomm, Inc. The concept of the CDMA system was later standardized by the Telecommunications Industry Association (TIA; n.d.) as an interim standard (IS-95). The CDMA system can use the same set of frequencies in every cell, which greatly improves the system capacity.

The increasing demand of supporting multimedia services over wireless systems triggered the design of new wireless systems and improvements of the GSM system. Several wideband wireless systems with higher data rates have been proposed since 2000, such as high-speed circuit-switched data (HSCSD), general packet radio service (GPRS), and enhanced data rates for GSM evolution (EDGE). In 2000, the GPRS system had its first trial. The GPRS system is an overlay system on top of the GSM network entities. It uses the same radio channels as GSM but with higher data rates. In order to harmonize global telecommunications, the design specifications of GSM successors began in 1998. International Mobile Telecommunications-2000 (IMT-2000) was proposed by the ITU, the United Nations organization responsible for global telecommunications. The objectives of IMT-2000 are to support multimedia applications over a family of wireless systems globally, standardize as many interfaces as possible, and provide compatibility to services within the IMT-2000 system (ITU n.d.). In 2001, the universal mobile telecommunications system (UMTS) was agreed upon as the European system for IMT-2000. UMTS was proposed by the 3rd-Generation Partnership Project (3GPP; n.d.) as a wideband, circuit- and packet-based transmission systems of text, digitized voice, video, and multimedia with data rates up to 2 Mbps (UMTS Forum n.d.). Currently, several third-generation wireless systems exist worldwide that provide both voice and data services.

Multiple Access: FDMA, TDMA, and CDMA

Multiple-access techniques provide a means of sharing the available bandwidth in the wireless system among multiple mobile users. Three major multiple-access techniques have been proposed for mobile cellular networks: FDMA, TDMA, and CDMA.

FDMA systems divide the available radio spectrum into multiple frequency bands. The width of each frequency band is a portion of the total available bandwidth. Different channels are assigned different frequency bands, as shown in Figure 1. Each user is allocated, on demand,

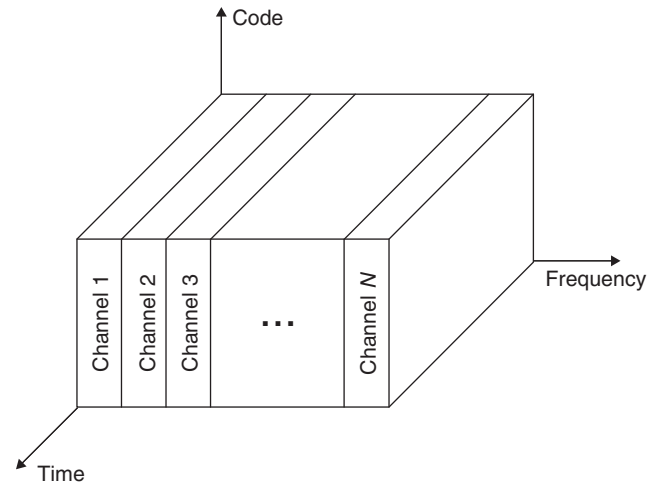

Figure 1: Frequency division multiple access (FDMA)

a unique frequency band or channel by the corresponding BS. During the period of the call, no other user can share the same channel. Multiple users inside the same cell must use different channels at the same time.

TDMA systems divide the available radio spectrum into multiple time slots. In each time slot, only one user is allowed to either transmit or receive. A physical channel is considered a particular time slot that reoccurs every frame, as shown in Figure 2, where N time slots comprise a frame. A TDMA frame is the basic unit of logic channels. Each user is allocated a unique time slot. Thus, the transmission of a user is noncontinuous, occupying a cyclically repeating time slot in every frame. TDMA shares a single-carrier frequency with multiple users, in which each user takes turns to use the nonoverlapping time slots.

In a CDMA system, all users may transmit simultaneously using the same carrier frequency, as shown in Figure 3. The narrowband signal from each user is multiplied by a very large bandwidth signal called spreading signal. Since the bandwidth of the spreading signal is much

Figure 2: Time division multiple access (TDMA)

Figure 3: Code division multiple access (CDMA)

larger than the bandwidth of the original information-bearing signal, the encoding process is known as spread-spectrum modulation and the resulting signal is also called a spread-spectrum signal. The spreading signal is a pseudo-random code sequence. Each user has its own pseudo-random code word, which is approximately orthogonal to all other code words. The receiver knows the code word used by the transmitter. Because of the existence of the orthogonal code words, the receiver can decode the desired signal correctly by performing a time correlation operation. All other code words appear as noise due to decorrelation. CDMA provides anti-jamming capability, privacy, resilience to interference, low probability of interception, and protection against multipath interference (Prasad and Ojanpera 1998).

Different Generations of Mobile Cellular Networks

First-generation (1G) cellular networks use analog transmission techniques to transmit analog voice signals. FDMA is adopted as the multiple-access technique for multiple users sharing the system-available bandwidth. Two separate frequency bands are assigned to each user for transmissions from the BS to the mobile phone (forward link or downlink) and from the mobile phone to the BS (reverse link or uplink). The second-generation (2G)

cellular networks use the digital transmission technique to transmit digital signals. TDMA or CDMA are adopted together with frequency division as the multiple-access techniques, which greatly increase the system capacity. Most of the 1G and 2G cellular networks are connected to the public switched telephone network (PSTN) to provide access to wireline telephones. The voice service is the major supported service of 1G and 2G cellular networks. Third-generation (3G) cellular networks are designed with the objective of supporting both voice and data services with higher data rates and quality. Wireless networks are connected to the PSTN for voice connections (circuit-switched services) and the Internet for data connections (packet-switched services). Second-and-a-half generation (2.5G) cellular networks, such as GPRS systems, use evolutionary technologies toward 3G by adding packet-switched entities to the existing circuit-switched domain of 2G in order to support both voice and data services. 2.5G can be considered a stepping stone between 2G and 3G wireless technologies.

Table 1 provides a mapping of various standards to different generations of cellular networks. The standards listed in the table will be explained in the following sections.

FIRST-GENERATION (1G) CELLULAR NETWORKS

First-generation cellular networks were widely deployed in the world in the 1980s. They were based on analog cellular standards (i.e., the radio signals of 1G cellular networks were analog). Frequency modulation (FM) was used to modulate analog voice signals to the carrier frequency for transmissions.

Major standards of 1G cellular networks include:

- AMPS, mainly used in the United States
- NMT, mainly used in northern Europe, eastern Europe, and Russia
- ETACS, used in the United Kingdom
- C-450, used in Germany, Portugal, and South Africa
- Radicom 2000, used in France

Advanced Mobile Phone System (AMPS)

AMPS was the first U.S. analog cellular system. It was developed by Bell Labs in the 1970s and considered a revolutionary accomplishment. From 1974 to 1978, a

Table 1: Standards for Different Generations of Cellular Networks

1G Cellular	2G Cellular	2.5G Cellular	3G Cellular
AMPS NMT-450 NMT-900 TACS ETACS C-450 Radicom 2000	GSM IS-54/IS-136 PDC IS-95/cdmaOne	HSCSD GPRS EDGE IS-95B	W-CDMA (UMTS) cdma2000 TD-SCDMA

large-scale AMPS trial was conducted in Chicago, and commercial AMPS service has been available since 1983. A total of 50 MHz in the 824–849 MHz and 869–894 MHz bands was allocated for AMPS. This spectrum was divided into 832 full-duplex channels (i.e., 832 for downlink and 832 for uplink), with a bandwidth of 30 kHz for each channel. Voice channels are assigned to radio frequencies using the FDMA technology; twenty-one channels are allocated for control. The control channels are data channels that operate at 10 kbps. The voice channels carry the conversation in analog using frequency modulation.

During the period of a call, each user is assigned a pair of duplex frequency channels with a 45 MHz split: one channel as the downlink and the other channel as the uplink. The simultaneous radio transmission and reception between a user and a BS is achieved by assigning a pair of duplex channels to each user. This is called frequency division duplexing (FDD). Simultaneous users are accommodated by giving each user a unique duplex channel. Therefore, AMPS is based on FDMA-FDD. When a call is completed, or when a handoff (the process of transferring an ongoing call from one channel to another; Akyildiz et al. 1999) occurs, the corresponding duplex channel is released so that other users may use it. Cells using different frequency channels form a cell cluster. The same set of frequencies is reused by cells in different clusters. In AMPS, the typical frequency reuse plan is either a twelve-cell cluster using omnidirectional antennas or a seven-cell cluster using three sectors per BS.

The coverage radius of one BS ranges from 2 kilometers to 20 kilometers. A signal-to-interference-ratio of 18 dB is required for satisfactory system performance. Table 2 lists the major parameters used in AMPS (Stallings 2005).

AMPS was widely deployed in the United States, Australia, the Philippines, and several other countries.

Table 2: AMPS Parameters

Base station transmission band	869–894 MHz
Mobile unit transmission band	824–849 MHz
Spacing between downlink and uplink	45 MHz
Channel bandwidth	30 kHz
Number of full-duplex voice channels	790
Number of full-duplex control channels	42
Mobile unit maximum power	3 watts
Cell radius	2–20 km
Modulation, voice channel	FM, 12-kHz peak deviation
Modulation, control channel	FSK, 8-kHz peak deviation
Data transmission rate	10 kbps
Error control coding	BCH (48, 36, 5) and (40, 28, 5)

However, the market share for AMPS continues to decline as digital systems become more prevalent (Rogers and Edwards 2003).

Nordic Mobile Telephone (NMT)

The NMT system was a 1G cellular network developed by Ericsson and deployed in the Nordic countries. It has been widely recognized as the first commercial cellular system in the world. The NMT system has two variants: NMT-450 and NMT-900. The NMT-450 system opened for service in Sweden and Norway in 1981, in Denmark and Finland in 1982, and in Iceland in 1986. It was optimized for use in areas of low population density. NMT-450 operated in the 450–470 MHz frequency bands with a 25 kHz channel bandwidth; the total number of duplex channels was 180. The NMT-900 system was introduced in 1986 with the operating frequency bands in 890–960 MHz and had been deployed for higher population density areas. The total number of duplex channels was 1,999, with a 12.5 kHz channel bandwidth. Both NMT-450 and NMT-900 systems used the FDMA technique for multiple access and frequency modulation for analog signal transmission. The cell sizes in an NMT system ranged from 2 kilometers to 30 kilometers. The NMT system was fully replaced by the GSM system in Europe except for limited use in rural areas. However, there are several initiatives to reopen the 450 MHz frequency band for 3G wireless services. In 2003, the NMT Association (NMTA; n.d.) reorganized and changed its name to the International 450 Association (IA450; n.d.) in order to reflect the focus on promoting the use of the frequency band 400 to 500 MHz for IMT-2000 digital wireless services.

Total Access Communications System (TACS) and European Total Access Communications System (ETACS)

TACS was the European version of AMPS. ETACS was an extended version of TACS with more channels and was mainly deployed in the United Kingdom. TACS was first introduced in 1982, operating in the 900 MHz frequency band. The channel bandwidth of TACS and ETACS was 25 kHz; the total number of duplex channels was 1,000 in TACS and 1,240 in ETACS. TACS and ETACS are now obsolete in Europe, having been replaced by the GSM system. In the United Kingdom, the ETACS service was discontinued in 2001.

Comparison of Major Standards

Table 3 gives a comparison of the major standards for 1G cellular networks using initialization year, frequency band, channel bandwidth, number of channels, and adopted countries (Rappaport 2002).

SECOND-GENERATION (2G) CELLULAR NETWORKS

2G cellular networks were first introduced in the early 1990s. In many countries, they were designed and deployed

Table 3: Comparison of 1G Analog Cellular Standards

Standard	Introduction on Year	Multiple Access	Modulation	Frequency Band (MHz)	Channel Bandwidth	# of Channels	Region
AMPS	1983	FDMA	FM	824–894	30 kHz	832	United States
NMT-450	1981	FDMA	FM	450–470	25 kHz	180	Europe
NMT-900	1986	FDMA	FM	890–960	12.5 kHz	1999	Europe
TACS	1982	FDMA	FM	890–960	25 kHz	1000	Europe
ETACS	1985	FDMA	FM	872–950	25 kHz	1240	United Kingdom
C-450	1985	FDMA	FM	450–465	10 kHz	573	Germany Portugal
Radicom 2000	1985	FDMA	FM	192–207 207–233 165–173 414–428	12.5 kHz	560 640 256 256	France

for conventional mobile telephone services as a high-capacity replacement for existing 1G cellular telephone networks. The main difference between 1G and 2G cellular networks is that the radio signals of 1G cellular networks are analog, whereas those of 2G cellular networks are digital. In 2G networks, the acoustic analog voice signals are first converted into digital signals. In order to use bandwidth more efficiently, compression is used to reduce the amount of digital information required to represent a digital voice signal. After that, digital transmission is used for transmitting the digital signal to the destination. Digital transmission is less susceptible to noise, compared to the analog transmission technique. The inherent benefits of using digital voice include that digital voice quality is independent of distance and it can be multiplexed into one channel, thus reducing cost. Hence, unlike 1G cellular networks that relied exclusively on FDMA/FDD and analog frequency modulation, 2G networks use digital modulations and TDMA/FDD and CDMA/FDD multiple-access techniques. 2G technologies offer at least a threefold increase in spectrum efficiency, so the system capacity is increased at least three times, compared to 1G analog technologies. Therefore, the number of customers supported by a 2G cellular system grows significantly.

2G standards can be divided into TDMA-based and CDMA-based standards depending on the type of multiple-access techniques used (Black 1999). The three major TDMA-based 2G standards and one CDMA-based 2G standard are:

- GSM (TDMA-based), originally from Europe, but used worldwide
- IS-136 or D-AMPS (TDMA-based, commonly referred as simply TDMA in the United States), used in the Americas
- PDC (TDMA-based), used exclusively in Japan
- IS-95 or cdmaOne (CDMA-based, commonly referred as simply CDMA in the United States), used in the Americas and parts of Asia

2G services are frequently referred to as a personal communications service (PCS) in the United States.

Global System for Mobile (GSM)

GSM is a pan-European digital cellular standard developed by ETSI (n.d.) and now maintained by the 3GPP. An important goal of the GSM development process was to offer compatibility of cellular services among European countries by providing a single unified standard. The GSM development process was similar to that of AMPS, except that no large-scale trial was conducted. The intellectual property rights of the GSM radio system from all vendors were waived, making GSM hugely popular.

Because there were many different first-generation systems in Europe, it was necessary to allocate a new frequency band for GSM. Most GSM networks operate in the 900 MHz or 1800 MHz frequency bands. Some countries in the Americas (including the United States and Canada) use the 850 MHz and 1900 MHz frequency bands because the 900 and 1800 MHz frequency bands were already allocated. In the 900 MHz band, the uplink frequency band is 890–915 MHz and the downlink frequency band is 935–960 MHz. This 25 MHz bandwidth is subdivided into 124 carrier frequency channels, each spaced 200 kHz apart. GSM combines both TDMA and FDMA. In GSM, a frequency carrier is divided into eight time slots, and the eight time slots are grouped into a TDMA frame. In a GSM BS, every pair of radio transceiver-receivers supports eight voice channels, whereas an AMPS BS needs one such pair for every voice channel. The channel data rate is 270.833 kbps and the TDMA frame duration is 4.615 ms (Goodman 1997; Garg and Wilkes 1999). There are four different cell sizes in a GSM network: macro, micro, pico, and umbrella cells. The coverage area of each cell varies according to the implementation environment. Macro cells are the cells in which the BS antenna is installed on a building above average rooftop level. Micro cells are the cells in which antenna height is under average rooftop level. Both types of cells are typically used in urban areas. Pico cells are small cells whose diameter is a few dozen meters; they are mainly used indoors. Umbrella cells are used to cover shadowed regions of smaller cells and to fill gaps in coverage between larger cells. The longest cell radius the GSM specification supports in practical use is 35 kilometers.

The transmission power in mobile phones is limited to a maximum of 2 watts in GSM850/900 and 1 watt in GSM1800/1900. GSM mobile phones control their output power to maintain interference at low levels. In addition, GSM introduced a subscriber identification module (SIM), which plugs into a card slot in the GSM handset and provides handset identification and additional security protection (ETSI/TC 1994a, 1997).

GSM is the most popular standard for mobile telephony in the world. GSM services are used by over 2 billion people across more than 210 countries (GSM World n.d.). The ubiquity of the GSM standard makes international roaming very common between mobile phone operators, enabling subscribers to use their phones in many parts of the world. The GSM roaming management protocol is specified by the GSM mobile application part (MAP), supporting handoff, paging, and location management (Rahnema 1993; Akyildiz et al. 1999; ETSI/TC 1994b).

In addition to connection-oriented voice services, GSM also provides the short message service (SMS), a connectionless transfer of messages with low-capacity and short-duration performance. In December 1992, the first short message sent from a personal computer to a mobile phone was delivered in the Vodafone GSM network in the United Kingdom (Lin and Chlamtac 2001). The SMS operates similar to the paging service. Short messages up to 140 octets are transported on the GSM stand-alone dedicated control channel (SDCCH) signaling channel and can be received while the mobile users are in conversation. Both the broadcast service, which periodically delivers short messages to all subscribers in a given area, and the point-to-point service (ETSI/TC 1994c), which delivers short messages to a specific user, are supported by GSM. Due to the potential for revenue, cellular providers have opened their networks to a number of additional services designed to increase SMS messaging volume. These additional services, such as e-mail, allow users across the Internet to contact mobile subscribers through SMS messaging without the use of a cell phone. However, the connections between the Internet and cellular networks introduce open functionality that detrimentally affects the fidelity of a cellular provider's service. The security impact of Internet-originated text messages on cellular voice and SMS services was discussed and evaluated in Enck et al. (2005).

IS-54/IS-136/D-AMPS

The Electronic Industries Alliance (EIA; n.d.) and TIA Interim Standard IS-136 is also referred to as digital advanced mobile phone system (D-AMPS), American digital cellular (ADC), or North American TDMA (NA-TDMA), the successor to IS-54. It is used throughout the Americas, particularly in the United States and Canada. IS-136 supports TDMA, which is similar to GSM and is considered as an evolutionary technology.

IS-136 is a digital extension of, and backward compatible with, AMPS. The IS-136 system operates in the same spectrum (824–849 and 869–894 MHz) with the same frequency spacing (30 kHz) used by the existing AMPS system. It allows smooth transition between digital and analog systems in the same area. Using TDMA, every IS-136 frequency carrier is divided into three time slots and supports three voice channels; thus, the IS-136 capacity is approximately three times greater than that of AMPS. The channel transmission bit rate for digitally modulating the carrier is 48.6 kbps. IS-136 uses the IS-41 standard (EIA/TIA 1991) for mobility management, which provides similar functionality to GSM MAP.

Personal Digital Cellular (PDC)

The personal digital cellular (PDC) standard is developed and used exclusively in Japan. As with D-AMPS and GSM, PDC systems also use the TDMA technology. The standard was defined in 1991 and launched in 1993 by NTT DoCoMo.

PDC systems are implemented in the 800 MHz frequency band (810–830 MHz for uplink and 940–960 MHz for downlink) as well as the 1.5 GHz frequency band (1429–1453 MHz for uplink and 1477–1501 MHz for downlink). The channel bandwidth is 25 kHz, and each carrier frequency is divided into three time slots. NEC and Ericsson are the major network equipment manufacturers.

In early 2005 PDC had about 56 million subscribers, following a peak of nearly 80 million (Yamauchi, Chen, and Wei 2005). It is slowly being replaced by 3G technologies such as W-CDMA and cdma2000.

Table 4 provides a comparison of the three major TDMA-based 2G digital cellular standards: GSM, IS-136, and PDC.

Table 4: Comparison of 2G Digital TDMA-Based Cellular Standards

Standard	Introduction Year	Multiple Access	Frequency Band	Channel Bandwidth	Channel Data Rate	# of Voice Channels	Regions
GSM	1990	TDMA/ FDMA/ FDD	890–960 MHz	200 kHz	270.833 kbps	1000	Worldwide
IS-136	1991	TDMA/ FDMA/ FDD	824–894 MHz	30 kHz	48.6 kbps	2500	The Americas
PDC	1993	TDMA/ FDMA/ FDD	810–960 or 1429–1501 MHz	25 kHz	42 kbps	3000	Japan

IS-95/cdmaOne

The EIA/TIA IS-95 (1993) digital cellular system was introduced by the TR45.5 subcommittee of the TIA in 1993 and has been operating in the United States since 1996. The brand name for IS-95 is cdmaOne. IS-95 is based on the CDMA technology that supports wideband signaling and offers increased capacity. The advantages of CDMA—such as multipath resistance, resilience to signal jamming, and privacy—make it especially attractive to military applications.

Similar to IS-136, IS-95 operates in the same frequency bands as AMPS (i.e., 824–849 MHz frequency bands for downlink and 869–894 MHz frequency bands for uplink). The channel bandwidth used by IS-95 is 1.25 MHz. This bandwidth is relatively narrow for a CDMA system, which makes the service migrations from analog to digital within an existing network more difficult than with AMPS and D-AMPS. The capacity of an IS-95 system is estimated to be ten times that of AMPS. Similar to AMPS, IS-95 uses the IS-41 standard for mobility management. Soft handoffs, during which a mobile phone is temporarily connected to more than one base station simultaneously, can be supported by the CDMA system.

IS-95 is currently used in the United States, South Korea, Canada, Mexico, India, Israel, Australia, Venezuela, and China.

SECOND-AND-A-HALF GENERATION (2.5G) CELLULAR NETWORKS

A 2G system is a digital mobile phone system and primarily transmits voice signals based on circuit-switched technologies, but it can also be used for circuit-switched data services as well (Black 1999). This circuit-switched data transmission limits data users to a single circuit-switched voice channel, and the data rate is limited to the voice channel data rate, which is too low for e-mail and Internet browsing applications. A 3G system is a mobile phone system that provides both packet-switched data services and circuit-switched voice services. Therefore, the term *second-and-a-half generation* (2.5G) is used to describe 2G systems that have implemented a packet-switched domain in addition to the existing circuit-switched domain. 2.5G can be considered a stepping stone between 2G and 3G wireless technologies.

2.5G standards are data-centric standards that can be overlaid upon existing 2G technologies. These standards allow existing 2G equipment to be modified and supplemented with new BS add-ons and subscriber unit software upgrades to support higher data rate transmissions for Web browsing and e-mail traffic. The 2.5G technologies also support a new Web browsing application using wireless application protocol (WAP), which allows standard Web pages to be viewed in a compressed format specifically designed for small and portable handheld wireless devices.

A wide range of 2.5G standards have been developed to allow each of the major 2G technologies (GSM, IS-136, and IS-95) to be upgraded incrementally for faster

Internet data rates. Following are the three major TDMA upgrade options:

- High-speed circuit-switched data
- General packet radio services
- Enhanced data rates for GSM evolution

High-Speed Circuit-Switched Data (HSCSD)

HSCSD is an enhancement to circuit-switched data, the original data transmission mechanism of the GSM system. It uses multiple time slots and/or different coding methods to increase data throughput. HSCSD allows individual data users to use multiple consecutive time slots in order to obtain higher-speed data access on the GSM network. It also allows different error-correction methods to be used for data transfer. HSCSD provides different levels of possible error correction that can be used according to the quality of the radio link. This means that under the best conditions, 14.4 kbps can be achieved through a single time slot, as compared to the original 9.6 kbps in the GSM specification. By using four consecutive time slots, HSCSD can provide a transmission rate of up to 57.6 kbps to individual users (four times 14.4 kbps). By combining up to eight GSM time slots, the capacity can be increased to 115 kbps (Rappaport 2002).

HSCSD requires the time slots being used to be fully reserved to a single user. However, voice calls have higher priority than HSCSD users. HSCSD users are typically charged based on the total period of time that a data connection is active, which is at a rate higher than a normal phone call (e.g., by the number of time slots allocated). This makes HSCSD relatively expensive in many GSM networks, because even during times when no data is being transferred, the bandwidth is unavailable to other potential users. This is one of the reasons that packet-switched GPRS, which typically has lower pricing (based on the amount of data transferred rather than the duration of the connection), has become more common than HSCSD.

General Packet Radio Services (GPRS)

GPRS is a packet-based data network for non-real-time Internet usage. It provides a packet network on dedicated GSM or IS-136 radio channels. GPRS retains the original modulation formats specified in the 2G TDMA standards but uses a redefined air interface in order to better handle packet data access (Rappaport 2002). Unlike HSCSD, which dedicates circuit-switched channels to specific users, GPRS supports multi-user network sharing of individual radio channels and time slots. This means that the total available bandwidth can be immediately dedicated to those users who are actually sending at any given moment, providing higher utilization. Therefore, GPRS can support many more users than HSCSD. Moreover, GPRS subscriber units are automatically instructed to tune to dedicated GPRS radio channels and particular time slots for “always-on” access to the network.

Packet-switched data under GPRS is achieved by allocating unused cell bandwidth to transmit data. When dedicated voice channels are set up by phones, the bandwidth available for packet-switched data reduces.

Hence, packet-switched data has a poor bit rate in busy cells.

Usually, GPRS data is billed per kilobytes of information transmitted. By using appropriate encoding schemes, GPRS can achieve a peak data rate of 21.4 kbps per channel per time slot. When all eight time slots of a GSM radio channel are dedicated to GPRS, an individual user is able to achieve as much as 171.2 kbps (eight times 21.4 kbps; ETSI/TC 1998a, 1998b).

Enhanced Data Rates for GSM Evolution (EDGE)

EDGE was first introduced to GSM networks around the world in 2003, initially in North America. EDGE is a more advanced upgrade to the GSM and IS-136 standards. It requires the addition of new hardware and software at existing BSs. EDGE introduces a new digital modulation technique, octal phase shift keying (8-PSK), which is used in addition to the GSM Gaussian minimum shift keying (GMSK) modulation. When EDGE uses 8-PSK modulation and all eight time slots of a GSM radio channel are dedicated to a single user, a raw peak data rate of 547.2 kbps can be achieved. In practice, the practical raw data rate is about 384 kbps for a single dedicated user on a single GSM channel (Furuskar et al. 1999). By combining the capacity of different radio channels, EDGE can provide up to several megabits per second of peak data rate to individual data users.

Whether EDGE is 2G or 3G depends on its implementation. EDGE can qualify as 3G services (because it can provide a data rate of above 144 kbps) but is considered by most to be a 2.5G service because the practical data rates are several times lower than true 3G services. Hence, EDGE is sometimes referred to as a 2.75G technology.

THIRD-GENERATION (3G) CELLULAR NETWORKS

Both 1G and 2G systems have been designed primarily for speech with low-bit-rate data services. The increasing number of Internet and multimedia applications is a major factor driving the third-generation wideband wireless technology. 3G mobile phone systems support 144 kbps data rate for users with high-speed mobility (e.g., in vehicles), 384 kbps for pedestrian users, and 2 Mbps for stationary users. The services include high-quality voice, wireless Internet access, and wireless multimedia services, which include audio, video, images, and data (3GPP 1999). 3G systems provide both a packet-switched and a circuit-switched domain from the beginning.

Work on 3G started around 1992, when the ITU formulated a plan to implement a global frequency band in the 2,000 MHz range that would support a single, ubiquitous wireless communication standard for all countries throughout the world. The new standard needed to be able to support a wide variety of mobile environments and have the flexibility to allow the introduction of new services and technologies (Zeng, Annamalai, and Bhargava 2000). This plan was renamed International Mobile Telecommunications-2000 (IMT-2000) in 1996. Figure 4 illustrates the ITU's view of a 3G system integrating disjoint networks and offering seamless services. In 1996, NTT and Ericsson initiated 3G development; in 1997, the U.S. TIA chose the CDMA technology for 3G; and in 1998, ETSI also selected the CDMA technology for 3G. In the same year, wideband CDMA (W-CDMA), cdma2000, and 3G time division duplexing (TDD) were proposed and developed by ETSI, the TIA TR45.5 subcommittee, and China/Europe, respectively.

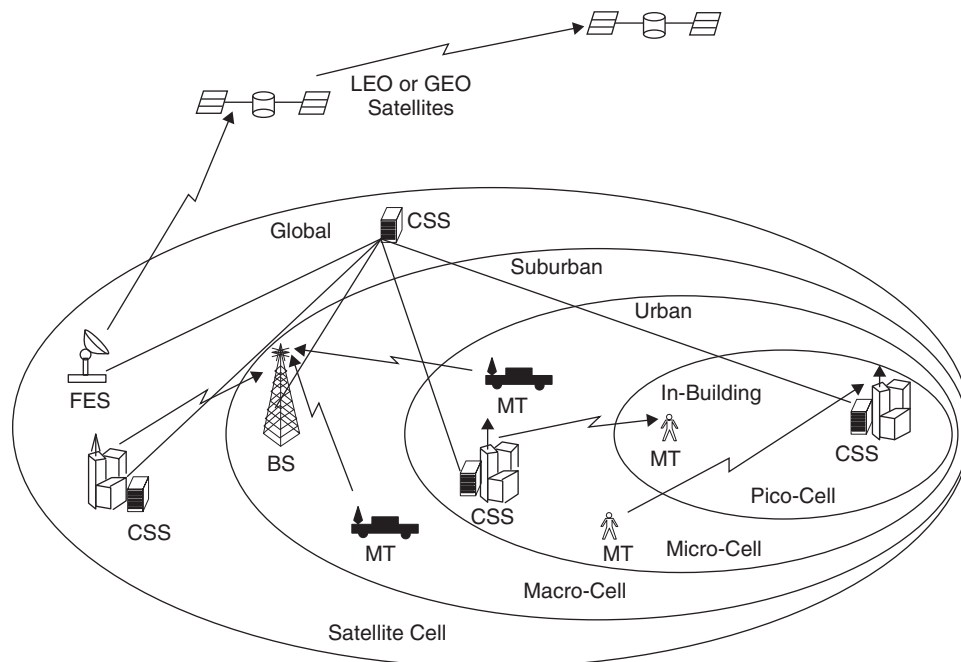

Figure 4: IMT-2000 integrated networks and services

Due to cost and complexity, the rollout of 3G has been much slower than anticipated. The spectrum licensing fees of 3G were collected many years before any income could be expected from 3G business. In addition, 3G requires a new access network, different from that already available in 2G systems. Hence, enormous investments are necessary to build the 3G networks. Therefore, many telecommunication operators encountered significant financial difficulties, which greatly delayed the 3G rollout in all countries except Japan and South Korea, where the spectrum licensing fees were avoided because priority was focused on national information technology (IT) infrastructure development.

The first country that introduced 3G on a large commercial scale was Japan. In 2005, about 40 percent of subscribers used 3G networks only, and currently 2G is on the way out in Japan. It is expected that the transition from 2G to 3G will be largely completed in Japan very soon, and upgrades to the next 3.5G stage with 3 Mbps data rates are under way.

The CDMA-based 3G standards selected from numerous proposals to ITU have become the major stream for IMT-2000. In particular, W-CDMA and cdma2000 are major 3G radio standards. W-CDMA was first developed by NTT DoCoMo, the predominant mobile phone operator in Japan, and later selected as the air interface for UMTS. The eventual 3G evolution for GSM, IS-136, and PDC systems leads to W-CDMA, whereas the eventual 3G evolution for 2G CDMA systems (i.e., IS-95) leads to cdma2000, a direct successor of IS-95. Several variants of cdma2000 are being developed, but all are based on the fundamentals of the IS-95 technology.

3G W-CDMA

In late 1996, ETSI developed the early versions of UMTS as a competitive open air-interface standard for 3G wireless telecommunications. In 1998, UMTS was submitted by ETSI to the ITU for consideration as a world standard for IMT-2000. W-CDMA is the technology behind the 3G UMTS standard (Ojanpera and Prasad 1998).

W-CDMA is a wideband spread-spectrum 3G mobile telecommunication air interface that utilizes code division multiple access. It is a complete set of specifications that includes a detailed protocol defining how a mobile phone communicates with the BS, how signals are modulated, and how datagrams are structured. In addition, system interfaces are specified to allow free competition on technology elements. The 3GPP standards body is developing W-CDMA for both wide-area mobile cellular coverage (using FDD) and indoor cordless type applications (using TDD).

W-CDMA is based on the direct spread CDMA technique. It requires a pair of a minimum spectrum allocation of 5 MHz, which is an important distinction from the other 3G standards. W-CDMA supports variable data rates up to 144 kbps for mobile vehicular data rate, up to 384 kbps for pedestrian data rate, and up to 2 Mbps for fixed data rate. Although W-CDMA is designed to provide backward compatibility and interoperability for all 2G and 2.5 G TDMA equipment and applications, the wider

air-interface bandwidth of W-CDMA requires a change of the RF equipment at each BS. Therefore, the installation of W-CDMA will likely be slow and gradual throughout the world.

3G cdma2000

Based on the original IS-95 (cdmaOne) CDMA standard, the cdma2000 3G standard allows wireless carriers to introduce a family of new high-data-rate Internet access capabilities in a gradual manner within existing systems, while assuring backward compatibility with existing cdmaOne subscriber equipment. Thus, current CDMA operators may seamlessly and selectively introduce 3G capabilities in each cell without having to change BSs.

The cdma2000 standard is being developed under the TIA working group 45 and involves the participation of 3GPP2. It is being developed for both FDD (mobile radio) and TDD (in-building cordless) applications. The first 3G CDMA air interface is cdma2000 1xRTT. It can support a typical data rate of up to 144 kbps per user and up to twice as many voice users as the 2G CDMA standard. When upgrading from 2G CDMA to cdma2000 1xRTT, only new backbone software and new channel cards at the BS need to be purchased. There is no need to change any RF system components at the BSs.

The cdma2000 1xEV is an evolutionary advancement for CDMA and has been adopted by many CDMA mobile phone service providers. It is standardized by 3GPP2 as part of the CDMA family of standards. The initial design of cdma2000 1xEV was developed by Qualcomm in 1999 to meet the IMT-2000 requirements as a high-data-rate packet standard to be overlaid on existing IS-95 networks. In August 2001, the ITU recognized cdma2000 1xEV as part of IMT-2000. The cdma2000 1xEV has two options for radio channels with data only (cdma 2000 1xEV-DO), and with data and voice (cdma 2000 1xEV-DV). Originally, 1xEV-DO referred to *1x evolution-data only* because it was a direct evolution of the 1xRTT air-interface standard, with its channels carrying only data traffic. Later, it was changed to mean *1x evolution-data optimized*.

Using cdma2000 1xEV technology, individual 1.25 MHz channels may be installed in CDMA BSs to provide high-speed data access within selected cells. Compared to the 1xRTT standard or the GPRS and EDGE networks, 1xEV-DO is significantly faster, supporting a data rate of greater than 2.4 Mbps per user (Bi et al. 2003). Only terminals with 1xEV-DO chipsets can take advantages of the higher speeds. The cdma2000 1xEV-DV supports both voice and data users with data rate up to 144 kbps and twice as many voice channels as IS-95.

3G TD-SCDMA

Time division-synchronous code division multiple access (TD-SCDMA) is a 3G standard being developed in China. In 1998, the China Academy of Telecommunications Technology (CATT) and Siemens Corporation jointly submitted an IMT-2000 3G standard proposal. This proposal was adopted by the ITU as one of the 3G options in late 1999. On January 20, 2006, the Ministry of Information

Industry of China formally announced TD-SCDMA as the country's standard of 3G mobile telecommunications.

TD-SCDMA relies on the existing core GSM infrastructure and allows a 3G network to evolve through the addition of high-data-rate equipment at each GSM BS. TD-SCDMA combines TDMA and TDD techniques to provide a data-only overlay in an existing GSM network (Li et al. 2005). TD-SCDMA supports a data rate of up to 384 kbps, and its radio channel bandwidth is 1.6 MHz. TD-SCDMA uses TDD, in contrast to the FDD scheme used by W-CDMA. With TDD, different time slots within a single frame on a single-carrier frequency are used to provide both downlink and uplink channel transmissions. By dynamically adjusting the number of timeslots used for downlink and uplink, the system can more easily accommodate asymmetric traffic with different data-rate requirements than FDD schemes. Because it does not require paired spectrum for downlink and uplink, spectrum allocation flexibility is also increased. In addition, the uplink signals are synchronized at the BS receiver, achieved by continuous timing adjustments. This reduces the interference between users of the same time slot using different codes. Therefore, the system capacity is increased, but at the cost of some hardware complexity in achieving uplink synchronization.

RECENT ADVANCES IN THE CELLULAR WORLD

3G and Beyond (B3G) Systems

In order to predict and define the next generation wireless system after 3G, shortcomings of 3G and necessary improvements need to be identified first. The first shortcoming is related to data rates. Current 3G systems can only support data rates up to 2 Mbps and limited multimedia services. No matter how fast the data rates a system can provide now, it will be a very slow system in ten years' time. According to the current 3G specifications, the realistic UMTS data rate is around 384 kbps. The 2 Mbps data rate can only be provided to low-mobility users in pico cells. For real-time multimedia services such as live high-definition video and music, more bandwidth and higher data rates are needed to deliver the service to mobile phones. Second, the FDD mode adopted by W-CDMA does not support asymmetric data connections very well. The FDD spectrum is paired and the same amount of spectrum is allocated for both directions. For services like Web surfing, multimedia applications, and e-shopping, traffic along the downlink will be much heavier than along the uplink. Therefore, using the FDD scheme, the downlink capacity will be in short supply but the uplink capacity will remain underused.

Several enhancements for 3G technologies, such as high-speed downlink packet access (HSDPA; included in UMTS standard release 5 published by 3GPP) and high-speed uplink packet access (HSUPA; included in UMTS standard release 6 published by 3GPP) were recently developed. HSDPA and HSUPA, often jointly referred to as HSxPA, provide a smooth evolutionary path for UMTS-based 3G networks supporting higher data transfer speeds. Current HSDPA deployments support 1.8 Mbps or 3.6 Mbps in

downlink, whereas HSUPA supports 5.76 Mbps for uplink. Under the HSDPA protocol, a new W-CDMA channel is defined: a high-speed downlink shared channel (HS-DSCH) that operates in a different way from existing W-CDMA channels. HSDPA achieves the increase in the data transfer speeds through adaptive modulation and coding, fast packet scheduling, and fast retransmissions (also known as hybrid automatic repeat request, or HARQ; 3GPP 2006). Similarly, HSUPA uses a new W-CDMA uplink channel, the enhanced dedicated channel (E-DCH), and employs similar link adaptation methods (adaptive modulation and fast scheduling) and HARQ to make retransmissions more effective. In addition, 3GPP is currently working on further advancing data rates. The UMTS terrestrial radio access network long-term evolution (UTRAN LTE), 3GPP's long-term evolution upgrade path for 3G systems, is expected to support 100 Mbps for downlink and 50 Mbps for uplink.

Fourth generation (4G) is often referred to as the successor wireless access technology to 3G. The Institute of Electrical and Electronics Engineers' (IEEE) official name for 4G is "3G and Beyond (B3G)." B3G is expected to provide users with on-demand, high-quality video and audio. B3G may use orthogonal frequency division multiplexing (OFDM) and orthogonal frequency division multiple access (OFDMA) to better allocate network resources to multiple users. B3G devices may use cognitive-radio-enabled or multimode receivers, which allow for better use of available bandwidth and use of multiple channels simultaneously. Unlike the 3G networks that include both circuit-switched and packet-switched networks, B3G will be based on packet switching only. This will allow low-latency data transmission.

The B3G technology will involve a collection of different kinds of multiple-access networks, such as 2G/3G cellular networks, wireless local area networks (WLANs), and Worldwide Interoperability for Microwave Access (WiMAX) networks (WiMAX Forum n.d.), from which a user can access the Internet by the most appropriate means. These networks must cooperate seamlessly and provide transparent applications to users. Both the network and the mobile devices will be able to configure themselves to adapt to different physical environments and transmission requirements. This includes software downloads for mobile devices to reconfigure themselves and the adaptability of networking protocols. Seamless vertical handoffs between different access networks will be supported for mobile devices to choose the best service provider and technology.

The major difference between 3G and B3G will be the all-packet-switched domain in B3G. The Internet will be the major backbone network connecting all kinds of wireless access networks for both voice and data services. Therefore, a B3G system is often referred to as an all-IP-based wireless system. The killer application of B3G is not clear, but consumers would expect from their mobile devices to receive all the multimedia applications they can receive from landline access, such as Internet access, voice over IP, music downloading, images, games, video, and mobile TV. However, since mobile phones are battery-constrained devices, power constraints have become a major concern for the newer-generation devices requesting multimedia services.

CONCLUSION

In this chapter, different generations of cellular networks—1G, 2G, 2.5G, 3G, and B3G—were reviewed. The historical evolution and main technical features of each generation were briefly introduced. The main difference between 1G and 2G cellular networks is that the radio signals of 1G cellular networks are analog, whereas those of 2G cellular networks are digital. The driving force of evolution from 2G to 2.5G, 3G, and B3G is the demand for mobile wireless access of data and multimedia applications. In addition, possible new features for the next-generation wireless system are also summarized in this chapter. This chapter aims to provide an overall picture of the evolution of the cellular technology. More technical details of some of the technologies mentioned in this chapter will be covered in the following chapters.

GLOSSARY

3GPP: 3rd-Generation Partnership Project.
AM: Amplitude modulation.
AMPS: Advanced mobile phone system.
CDMA: Code division multiple access.
EDGE: Enhanced data rates for GSM evolution.
ETACS: European total access cellular system.
ETSI: European Telecommunications Standard Institute.
FDD: Frequency division duplexing.
FDMA: Frequency division multiple access.
GPRS: General packet radio service.
GSM: Group Special Mobile/global system for mobile communications.
HSCSD: High-speed circuit-switched data.
HSDPA: High-speed downlink packet access.
HSUPA: High-speed uplink packet access.
IMT-2000: International Mobile Telecommunications-2000.
ITU: International Telecommunications Union.
NMT: Nordic mobile telephone.
OFDM: Orthogonal frequency division multiplexing.
OFDMA: Orthogonal frequency division multiple access.
PCS: Personal communications service.
PSTN: Public switched telephone network.
SIM: Subscriber identification module.
SDCCH: Stand-alone dedicated control channel.
SMS: Short message service.
TDD: Time division duplexing.
TDMA: Time division multiple access.
UMTS: Universal mobile telecommunications system.

INTRODUCTION

The *global system for mobile* (GSM) communications is the world's first cellular system to specify digital modulation and to have digital technology for both signaling and speech channels. Therefore, it is considered a *second-generation* (2G) mobile phone system. Nevertheless, GSM has undergone evolutions of twenty-one 2G and *third-generation* (3G) enhancements from *general packet radio services* (GPRS), *enhanced data rates for GSM evolution* (EDGE), to *universal mobile telecommunications system* (UMTS). These subsequent advancements are backward-compatible with GSM while adding new capabilities. The release 1997 version added packet data capabilities with GPRS. In 1998, the *3rd Generation Partnership Project* (3GPP) was formed. Originally, it was intended only to produce the specifications of the third generation of mobile networks. However, 3GPP also took over the maintenance and development of the GSM specification. Higher speeds were added using EDGE in release 1999. In this introduction, we provide a brief history of GSM's development.

During the early evolution of cellular mobile communication, systems were developed without paying much attention to standardized specifications. In 1982, a committee was formed with the French name *Groupe Spéciale Mobile* (GSM) under the umbrella of the *Conference of European Posts and Telegraphs* (CEPT). The purpose has been to define a new standard for mobile communications in the 900-MHz range. This was to serve as the standard for pan-European cellular service. In 1991, the acronym GSM changed to stand for global system for mobile communications; this was the year the first GSM system was ready for user-friendly operation. CEPT has now evolved into

the organization called the *European Telecommunications Standards Institute* (ETSI).

The proposed system had to meet a set of criteria including subjective speech quality, low terminal and service cost, support for international roaming, the ability to support handheld terminals, support for range of new services and facilities, spectral efficiency, and *integrated services digital network* (ISDN) compatibility.

Following the discussions during 1982 to 1985, a digital system was adopted for GSM. The technical fundamentals of the GSM system were defined in 1987. This included the choice of the narrowband *time-division multiple access* (TDMA) as the multiple access technique. In 1989, ETSI took over control, and by 1990 the first GSM specification amounting to more than 6000 pages of text was completed. Phase 1 GSM 900 specifications were also frozen that year. The variation of GSM system named *Digital Cellular System 1800* (DCS 1800), operating in the 1800-MHz frequency range, also was finalized this year to be used in the United Kingdom. DCS 1800 was adapted to operate in the 1900-MHz band in the United States, where it is called *Personal Communication System 1900* (PCS 1900).

By 1992, many European countries had operational networks based on GSM and started to have worldwide penetration. The first GSM network operator was Oy Radiolinja Ab in Finland in January 1992. Following the success of GSM in Europe in 1992, the first demonstration in Africa took place in 1993 at Telkom 1993 in Cape Town, and the first GSM network in Africa was launched in South Africa in 1994. During 1993 to 1997, more and more countries and regions around the world adopted GSM. The first PCS 1900 network went live "on air" in the United States,

and the U.S. Federal Communications Commission auctioned off PCS licenses. In an industry conference, Telecom 1995, in Geneva, Nokia showed 33.6-kbps multimedia data transmission via GSM. The phase 2 of the standard was completed in 1995, and the fax, data, and *short message service* (SMS) roaming also were included that year.

In 1996, the 8-K subscriber identity module was launched, and prepaid GSM SIM cards were available. A SIM is a smart card that securely stores the key that identifies a mobile phone service subscriber as well as subscription information, preferences, and text messages. The SIM stores network state information such as its current *location area identity* (LAI). If the handset is turned off and back on again, it will take data off the SIM and search for the LAI it was in. Each SIM is uniquely identified by its international circuit card ID. SIM cards identify users uniquely by holding an *international mobile subscriber identity* (IMSI). SIM is further discussed below under "Mobile Station Subsystem." The first dual-band GSM 900-1900 phone was launched in 1997. In 1998, Vodacom introduced free voicemail.

Market Penetration of GSM

As this chapter is written, GSM service is used by more than 1.6 billion people across more than 210 countries and territories. Originally developed to serve as the pan-European cellular service, GSM is now the world's most popular standard for cellular radio and personal communication services. The growth was rapid. In December 1992, there were thirteen networks on the air in seven areas, and the GSM world congress in Berlin consisted of 630 participants. By December 1993, there were thirty-two networks on the air in eighteen areas, and there were 760 participants in the GSM world congress in Lisbon. There were 780 participants in the GSM world congress in Athens. By December 1994, there were sixty-nine networks on the air in forty-three areas. In 1995, the world congress in Madrid has had 1400 participants; by December, there were 117 networks in sixty-nine areas. In December 1996, there were 120 networks on the air in eighty-four areas. By December 1998, there were 125 million GSM 900, 1800, and 1900 users worldwide. This number grew to 165 million in 1999, 480 million in 2000, and 500 million in 2001. By 2001, there were 500 million GSM users (CellularOne, undated).

The widespread use of the GSM standard makes international roaming possible, and the subscribers are able to use the same mobile communication devices in different parts of the world with ease. GSM is an open standard that is currently developed by the 3GPP. More than 1.6 billion people used GSM phones as of 2005, making GSM the dominant mobile phone system worldwide with approximately 78 percent of the world's digital mobile market and 75 percent of the world's wireless market (GSM World, undated). GSM's main competitor, cdmaOne, is used primarily in North America and parts of Asia (Heine 1998). cdmaOne also benefited from increased radio spectrum efficiencies compared with the more common GSM networks. Roaming with GSM phones is a major

advantage over the competing technology because roaming across CDMA networks with different operators is difficult, depending on the handsets and operators concerned. However, as pointed out in the sections to follow, there are limitations to the level of roaming in terms of geographical areas and regions because of commercial and licensing reasons. Furthermore, the standards do not fully specify some elements and different implementations by different vendors which may hinder interoperability. Another major reason for the growth in GSM usage, particularly between 1998 and 2002, was the availability of prepaid calling from mobile phone operators. This allows people who are either unable or unwilling to enter into a contract with an operator to have mobile phones. For example, students and teenagers can get prepaid accounts that they can manage themselves without needing parents to manage and sign for contracted accounts. It also allows some operators to offer solutions for infrequent users who are likely to spend less per month on prepaid accounts than on minimum basic service plans. Prepaid accounts also enabled the rapid expansion of GSM in many developing countries where large sections of the population do not have access to banks or bank accounts and countries where there are no effective credit rating agencies. (In many developed countries, starting a non-prepaid contract with a cellular phone operator is almost always subject to credit verification through personal information provided by credit rating agencies).

GSM was also the first to have SMS text messaging, which proved extremely popular with the teenage market.

Factors Contributing to the Success of GSM

The major factors that have contributed to the commercial success of GSM systems manufacturers and network operators are:

- the liberation of the monopoly of telecommunications in Europe during the 1990s, which led to competition and hence lower prices;
- the knowledge base and professional approach within the GSM committee and the active cooperation of the industry; and
- the lack of competitions from other parts of the world at the time of GSM was being developed.

The GSM specifications define the functions and interface requirements in detail but do not address the hardware. The reason for this is to not limit designers yet still make it possible for operators to buy equipment from different suppliers. Further, it is the first standard to specify the network-level architecture and services for mobile communication systems.

From the point of view of the consumer, the key advantage of GSM systems has been higher digital voice quality and low-cost alternatives to making calls such as text messaging. The advantage for network operators has been that the vendors can address a large market, allowing easy interoperability. Also, the open standards have allowed

network operators to offer roaming services, which means subscribers can use their phones all over the world.

GSM SERVICES

GSM services can be grouped into three categories: *teleservices* (TS), *bearer services* (BS), and *supplementary services* (SS). In essence, TS is telephony, BS the data transmission, and SS the value-added features.

Teleservices

TS includes bidirectional telephony, emergency calls, and voice messaging. An emergency call feature allows the mobile subscriber to contact a nearby emergency service, such as police, by dialing a unique number. Voice messaging permits a message to be in the voice mailbox when the called party is not reachable.

Bearer Services

BS includes data services (with data terminals or computers connected to the mobile devices), short message service, cell broadcasting, and local features. Rates as high as 9.6 kbit/s are supported. With a suitable data terminal or computer connected directly to the mobile apparatus, data may be sent through circuit-switched or packet-switched networks. For SMS (as many as 160 alphanumeric characters), a message center is involved. The broadcast mode is used to send a message to all subscribers in a given geographic area. This service also can be used for short messages of as many as ninety-three characters. Local features of the mobile terminal include abbreviated dialing, editing of short messages, and repetition of failed calls.

Supplementary Services

Some of the SS are as follows:

- advice of any charges (i.e., the cost of a call in progress);
- blocking of all outgoing calls;
- blocking of incoming or outgoing international calls as a whole or only those associated with a specific basic service as desired;
- blocking of roaming calls (e.g., all incoming roaming calls or only those associated with a specific service);
- call forwarding of all incoming calls, or only those associated with a specific basic service, to another directory number (forwarding may be unconditional or be set to take place when the mobile subscriber is busy, there is no reply, the mobile subscriber is not reachable, or there is radio congestion);
- call holding, or allowing interruption of an existing call with subsequent reestablishment of the call permitted;
- call waiting, or allowing the notification of an incoming call when the mobile subscriber is busy;
- call transfer, which permits an established incoming or outgoing call to be transferred to a third party;
- call completion to busy subscribers, which allows notification when a busy called subscriber becomes free and call reinitiation if desired;
- closed user group, which allows a group of subscribers to communicate only among themselves;

- calling number identification presentation or restriction, which permits or restricts the presentation of the calling party;
- SS identification number (or additional address information);
- connected number identification presentation, which indicates that the phone number that has been reached;
- free-phone service, which allocates a number to a mobile subscriber, with all calls to that number free of charge for the calling party;
- malicious call identification, which permits the registration of malicious, nuisance, and obscene incoming calls; and
- three-party service, which permits the establishment of conference calls.

The GSM project embraces an ambitious set of targets—namely, international roaming, open architecture, high degree of flexibility, easy installation, interoperability with ISDN, the *circuit-switched public data network* (CSPDN), the *packet-switched public data network* (PSPDN), and the *public switched telephone network* (PSTN), high-quality signal and link integrity, good spectral efficiency, low-cost infrastructure, small terminals, and security features. These objectives have been gradually achieved, and a broad collection of services are provided.

NETWORK ARCHITECTURE

GSM uses the cellular communication structure in which a geographical area to be served is partitioned into subareas called *cells*. A *mobile station* (MS) within a cell achieves connectivity to the network via a *base transceiver station* (BTS) with limited transmission range. The frequency spectrum available to an operator is divided into narrow band frequency channels. Each cell is assigned a subset of the set of channels according to a frequency plan. The frequency plan achieves good reuse of channels to control the co-channel interference and maximize the capacity with a given set of cells. As the demand for service is increased, the cells are split into smaller cells, thus increasing the network capacity. Another technique is to divide the cells into sectors with one transceiver for each sector. The transceivers for all of the sectors in a cell can be co-located and therefore can be part of the same base station. Figure 1 illustrates cellular structure, frequency reuse, and cell splitting.

Figure 1: Cellular structure, frequency reuse, and cell splitting

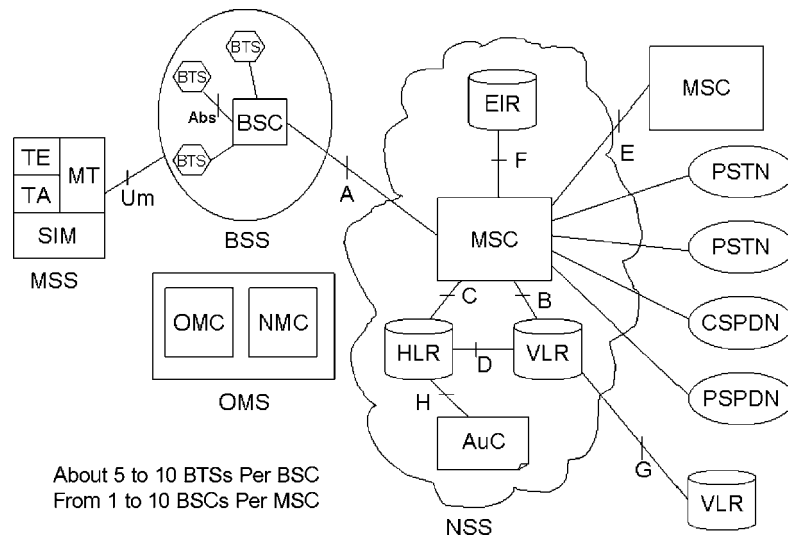

Figure 2: The GSM networks architecture

A mobile station in a cell establishes connection to another MS within the same cell, an MS in another cell, or to a wired telephone via the base station covering the cell. As the mobile station moves from one cell to another, a handover process is invoked and the connection is made via the base station in the new cell. This process as well as many other network-related communication overheads are handled in GSM with a modular and hierarchical network structure. The required computations and communications are performed with distributed computer systems as opposed to a central computer.

GSM Subsystems

A GSM network is made up of the *mobile station subsystem* (MSS), the *base station subsystem* (BSS), the *network and switching subsystem* (NSS), and the *operation and support subsystem* (OSS). All of these entities form a *public land mobile network* (PLMN). Figure 2 describes schematically the various subsystems and the components of subsystems of a GSM PLMN. Also shown are the various interfaces to be described later. The components of each subsystem are described here.

Mobile Station Subsystem

The MSS includes the *terminal equipment* (TE), the *terminal adapter* (TA), the *mobile termination* (MT), and a *subscriber identity module* (SIM). TE, TA, and MT compose the *mobile equipment* (ME), and SIM enables its use. A device such as a fax or a computer may be considered a TE. An MT incorporates the standard GSM mobile terminal functions. A TA works as an interface between the TE and the MT.

GSM Recommendation 02.07 describes in detail the mandatory and optional functionalities of mobile equipment. The most important features are *dual tone multifrequency* (DTMF) capability, SMS capability, availability of the ciphering algorithms A5/1 and A5/2, display capability for short messages, dialed numbers, available PLMN, support for emergency calls (without SIM), and an *international mobile equipment identifier* (IMEI). These devices may be fully or partially integrated into one piece. In addition to its IMEI, the mobile equipment is identified

Figure 3: The GSM plug-in SIM

through its classmark, which includes the revision level, encryption capability, frequency capability, short message capability, and *radio frequency* (RF) power capability. There are five MSS classes in GSM 900 based on the maximum RF power. The maximum RF power levels for classes I, II, III, IV, and V are 20, 8, 5, 2, and 0.8 watts, respectively. Class I GSM 900 devices are no longer used. DCS 1800 and PCS 1900 have power levels of 1 and 0.25 watts for classes I and II, respectively. Class III DCS 1800 has a power level of 4 watts, whereas a class III PCS 1900 has a power level of 2 watts.

In GSM, the mobile station is distinguished from mobile equipment by the SIM. The GSM allows the use of mobile phone (mobile equipment) without SIM only for emergency calls. The mobile equipment and SIM together form the MS (see Figure 3). SIM is a microchip planted in one of the two forms, the check card (ID-1 SIM), which is the size of a credit card and can be inserted into larger equipment such as a car phone or the smaller (approximately 2.5 cm × 1.5 cm) plug-in SIM (Rappaport 1996). Both versions are functionally same.

The SIM holds various data related to the subscriber as described in Table 1.

Part of data are subscriber information such as the *international mobile subscriber identity*. Parameters such as *personal identification number* (PIN) and *PIN unblocking key* (PUK) are needed for administrative tasks. Others

Table 1: Data on a SIM

Purpose	Parameters	Description
Administrative	PIN/PIN2 PUK/PUK2 SIM service table Last dialed number Charging meter Language	Personal identification number PIN unblocking key Optional functionality Redial Charges, increments Prompts by the mobile station
Security	Algorithm A3 and A8 Key K_i Key K_c CKSN	Authentication to find K_c Only on SIM and HLR Ciphering key sequence number
Subscriber data	IMSI (international mobile subscriber identity) MSISDN (mobile subscriber ISDN) Access control class(es)	Directory number of a subscriber For control of network access
Roaming data	TMSI T3212 Location updating status LAI Network color codes (NCCs) of restricted PLMNs NCCs of preferred PLMNs	Temporary mobile subscriber identity For location updating Is location updating required? Location area information
PLMN data	NCC, mobile country code (MCC) Mobile network code (MNC) of the home PLMN Absolute radio frequency channel numbers (ARFCNs) of home PLMN	Network identifier Frequencies for which the home PLMN is licensed

are used in functionalities related to security and roaming. As for the security-related parameters, the key K_i is subscriber-specific and is only on SIMs and *home location registers* (HLRs). The key K_c is the result of algorithm A8, K_i , and a *random number* (RAND).

Base Station Subsystem

The BSS is responsible for the radio coverage of a given geographic region and for appropriate signal processing. As the MS moves from one cell to another, the connection is transferred to the next BTS (i.e., the handover). The BSS consists of one or more base transceiver stations, a *base station controller* (BSC), and a transcoding rate and adaptation unit. Although the size of a BTS has diminished over time, the functionalities remains more or less the same as in the original systems. A BTS contains one or more *transmitter and receiver* (TRX) modules, an *operation and maintenance* (O&M) module with a clock module, and input-output filters. GSM recommendation allows as many as sixteen TRXs. The O&M module of a BTS is directly connected to the BSC, which allows this module to process the commands from the BSC or the *mobile switching center* (MSC) directly into the BTS and to report the results. It also includes a human-machine interface for local control of BTS. The internal clock of GSM BST is required for testing in a stand-alone environment or when the connection to BSC's pulse code modulation clock is not available. All of the TRXs of a BTS are required to use the same clock signal. The required accuracy of the clock is defined to be 0.05 parts per million. This translates to $\pm 0.5\text{Hz}$ at a clock speed of 10 MHz. The input-output filters limit the

bandwidth of the receiver-transmitter signals. The input filters on the uplink (MS to BTS) are fixed wideband filters designed to pass GSM 900, DCS 1800, or PCS 1900 frequencies. On the downlink (BTS to MS), the output filters have bandwidths of 200 kHz and are remotely controllable by the operation and maintenance center (OMC).

Network and Switching Subsystem

The NSS carries out the GSM switching procedures and the manipulation of the databases for mobility management of the subscribers. Its functions include coordination of call setup, paging, resource allocation, location registration, encryption, interfacing with other networks, handover control, billing, and synchronization, among others. The NSS consists of the MSC, the HLR, the *visitor location register* (VLR), the *authentication center* (AuC), and the *equipment identity register* (EIR).

The MSC performs the switching functions and coordinates all of the calls and routing procedures within GSM. In general, an MSC controls several BSSs. Thus, it is responsible for traffic management and the radio coverage of a given geographic area—the MSC area. A GSM network may have one or more MSCs, depending on the traffic to be controlled. An MSC is responsible for several functions such as paging, coordination of call setup, allocation of resources, interworking with other networks, handover management, billing, encryption, echo canceling, control, and synchronization with BSSs, among others. It interfaces the GSM PLMN with the external networks such as PSTN, ISDN, CSPDN, and PSPDN. Such interfacing may

be carried out through a gateway MSC connected to a serving MSC.

The HLR is a database that contains a list of those subscribers who belong to one or more MSC areas within which they have originally been registered. An HLR, therefore, defines the subscription area. In the HLR, these subscribers are associated with information records that are relevant to call management. Both permanent and temporary data are held within the HLR. The permanent data constitute data that are modified only for administrative reasons and are kept for every call. The temporary data are modified to accommodate the transient status of the subscribers' parameters and can be changed from call to call. The permanent data include IMSI, MS-ISDN, information on roaming restriction, permitted supplementary services, and an authentication key for security procedures. The temporary data consist of MSRN, data related to ciphering, the VLR address, the MSC address, and information on roaming restrictions. An HLR is usually centralized, but it can also be distributed within the network, with the configuration chosen in accordance with the operator's needs.

The VLR is a database that contains a list of those subscribers belonging to another subscription area but who are now in roaming condition within this MSC area. In the VLR, these roaming subscribers are associated with information records relevant to the call management. In essence, the VLR contains the same information associated with the HLR. In fact, when a subscriber roams into another MSC area, the relevant data belonging to this subscriber stored in the HLR are transferred to the corresponding VLR. The data of the roaming subscriber, retrieved from the HLR, remain in the respective VLR as long as the subscriber is found in a roaming condition. A VLR is usually co-located with the MSC.

The AuC is a functional entity that manipulates the authentication functions and encryption keys for each subscriber within the system. An authentication key, kept in the SIM card and in the AuC, is provided for each subscriber in the system and is never transmitted over the air. Instead, a random challenge and the response to this challenge are transmitted (to be detailed later). The random challenge and the respective response are based on authentication keys and ciphering algorithms. Note that the contents of the information exchanged in such a procedure may change for each call. In conjunction with the *temporary mobile subscriber identity* (TMSI), this constitutes an interesting procedure that renders GSM robust with respect to unauthorized accesses. On the other hand, vulnerability is present when the authentication key must be transmitted from an HLR to a VLR in a roaming situation. The EIR is a database that contains the IMEIs of all subscribers. The IMEIs are grouped into three categories:

1. a white list, which contains the IMEIs known to belong to equipment with no problems;
2. a black list, which contains the IMEIs of equipment that has been reported stolen; and
3. a gray list, which contains the IMEIs of equipment with problems that are not substantial enough to warrant barring.

Operation and Support Subsystem

The OSS performs the operation and maintenance functions through two entities, namely, the OMC and the *network management center* (NMC). The GSM standards do not fully specify these elements. Therefore, different manufacturers may have different implementations, which may be a problem for interoperability between different GSM systems. The NSS uses lines leased on the PSTN or other fixed networks to communicate with the GSM entities. Protocols used for data transfer are SS7 and X.25. In general, the O&M functions performed by the OSS include alarm handling, fault management, performance management, configuration control, and traffic data acquisition, among others. In many circumstances, the actions may be taken remotely and automatically and, on detection of an abnormal operation, tests, diagnoses, and fault removal can be carried out to place the system back in service.

The network resources may be activated or deactivated via the OMC functions. There may be one or several OMCs, depending on the size of the network. An OMC is a regional entity used for daily maintenance activities. The NMC serves the entire network. It performs a centralized network management and is used for long-term planning.

INTERFACES

Several interfaces are defined in GSM standards for communication between different components of the GSM network as shown in Figure 2. They are called *open interfaces* and allow the choice of equipment from different vendors. Eight of these interfaces are named by uppercase letters A through H. There are two others—namely, Abis-interface and Um-interface. Each interface is briefly described here.

A-interface is the interface between BSC and MSC. It supports signaling and traffic (voice and data) information transmitted by means of one or more 2.048-Mbit/s transmission systems. The Abis-interface is defined for the communication between BTS and BSC. It handles common control functions within a BTS. It is physically supported by a digital link using the *link access protocol for the ISDN D-channel* (LAPD). The Um-interface, or air interface, defines the standards for the interface between MSS and BSS. The physical and logical channel structure as well as the frame hierarchy are part of the definitions of this interface. The remaining interfaces are as follows.

- B: between MSC and VLR.
- C: between MSC and HLR.
- D: between HLR and VLR.
- E: between MSCs.
- F: between MSC and EIR.
- G: between VLRs.
- H: between HLR and AuC.

The great majority of the GSM interfaces make use of well-consolidated protocols such as SS7, X.25, and LAPD (the ISDN data-link layer). The 2.048-Mbit/s E1 digital links are used to interconnect the several GSM elements and external elements. For example, E1 is used to

interconnect MSC and PSTN, MSC and MSC, and BSC and MSC. Each E1 channel is then used to convey payload information or control information. The control information may use protocols such as SS7, LAPD, and X.25.

SPECTRAL EFFICIENCY

In this section, we discuss the techniques used in the physical and radio link layers to optimize spectral efficiency. This includes signal processing, the transmitter-receiver chain, equalization, frequency hopping, discontinuous transmission with speech activity detection, and power control.

Signal-Processing Functions

As a fully digital system, GSM mobile equipment employs analog-to-digital conversion at transmission on the uplink and digital-to-analog conversion at reception on the downlink. To this end, GSM adopts a sampling rate of 8 kHz and uniform quantization with thirteen bits per sample leading to a raw rate of $8 \times 13 = 104$ kbit/s. This rate is reduced to 13 kbit/s using a speech coding algorithm—namely, regular pulse excitation and long-term prediction linear prediction coding. This is followed by a forward error-correction code block and an interleaver to minimize burst errors. In particular a $1/2$ rate convolution code is used. Following this process, a channel rate of 270.833 kbit/s is achieved. The resulting binary bit stream is carrier modulated using *Gaussian minimum shift keying* (GMSK) scheme and is transmitted through the wireless channel. The receiver chain on the uplink at the base station consists of a demodulator, a deinterleaver, an error-correction block, and a decoder to convert 13-bit uniform to 8-bit A law, leading to a raw bit rate of 64 kbit/s. The bit stream is then transmitted to MSC. For the downlink direction, the signal processing functions take place in the reverse order and ends with a digital-to-analog conversion at the mobile station.

Multipath Equalization

RF signals in the 900-MHz band are reflected or refracted from objects in the environment such as buildings, cars, and hills. Many such reflected signals, each with a different phase, can superimpose constructively and destructively at the receiver antenna, leading to multipath fading phenomena. *Equalization* refers to signal processing used to undo the distortion introduced by this effect. It works by finding out how a known transmitted signal is modified by multipath fading and then constructing an inverse filter to extract the rest of the desired signal. This known signal is the 26-bit training sequence transmitted in the middle of every time-slot burst. The actual implementation of the equalizer is not specified in the GSM specifications.

Frequency Hopping

To further improve frequency reuse planning, GSM uses *frequency hopping* (FH) and slow FH in particular. Although FH is available in all GSM mobile equipment, its use is up to the operator. With slow FH, the transmission in a given

time slot moves from one GSM frequency carrier to another, according to a hopping pattern. The hopping takes place for each frame of duration 4.615 ms. As the number of frequencies utilized increases, the probability of encountering more than one faded frequency at the same time diminishes. Therefore, with FH, the transmission becomes less vulnerable to fading. Further, if the co-channel cells are assigned different hopping sequences, then the co-channel interference may reduce. The hopping can take place on any carrier in the GSM band except the standard broadcast carrier (base channel). To achieve these desired results, the signals within a group of cells are required to use mutually orthogonal hopping sequences. This, in turn, requires coordination among all of the signals. Both the uplink and the downlink operate with the same FH sequence. When a terminal is to use FH, it is informed by the network on the available set of hopping channels and the hopping sequence number.

Discontinuous Transmission

In a normal conversation, the voice activity factor is less than 60 percent on average. Therefore, switching the transmitter off during the inactive period can significantly save battery power and also help reduce interference (thereby increasing the user capacity). To achieve this, GSM equipment is designed for *discontinuous transmission* (DTx). The implementation includes a *voice activity detector* (VAD), which plays a decisive role in transmission performance. When it detects voice (in the presence of noise) or noise, the VAD outputs a signal to control a transmitter switch. A decision in favor of a wrong detection will produce annoying effects in the transmission such as a clipping in speech. As the transmitter is switched off between talkspurts, at the receiving end the background acoustic noise present during the conversation abruptly disappears. It has been observed that this also can be annoying to the listener. To minimize the effect of such a noise “modulation,” a synthetic signal known as a *comfort noise signal* (CNS), which has characteristics that match those of the background noise, is introduced at the receiver. It tries to conform with the characteristics of the background noise of the current transmission. To accomplish this, the noise parameters are computed at the transmit end during a time span of four frames after the VAD detects the end of a talkspurt. These parameters are sent to recompose the noise at the receiver. In addition to VAD and CNS, the DTx implementation includes *speech frame extrapolation* (SFE) function. The SFE aims to replace a speech frame that has been badly corrupted by error with a preceding uncorrupted speech frame. This replacement is based on the fact that consecutive speech frames are highly correlated. The use of SFE improves the signal quality (i.e., improves mean opinion score).

Power Control

Power control can be used to reduce co-channel interference and increase battery life. The GSM standard allows power control at both uplink and downlink. Power control requires periodic feedback signaling from the receiver to transmitter. In GSM, the mobile power can be

adjusted in steps of 2 dB from a minimum of 13 dBm (20 mW) to as high as 30 dB, resulting in sixteen power levels. Power adjustment can take place for every 60 ms corresponding to thirteen frames. In comparison to CDMA, where the power control resolution is 1dB or lower, this appears to be coarse.

Spectral Efficiency of GSM

Efficient signal-processing stages used in GSM such as adaptive equalization, error-correction codes, GMSK modulation, and SFE makes it possible to operate at low carrier to interference ratio and therefore allows small frequency reuse clusters of three or four cells. The spectral efficiency in terms of users per cell per MHz for a typical scenario can be calculated as follows. In GSM 900, for instance, there are 50 MHz of spectrum and 124 pairs of frequency channels. Because each frequency channel has eight time slots, there are $8 \times 124 = 992$ combinations of frequency channels and time slots, allowing that many simultaneous users. With a frequency reuse cluster size of four and thus a spectral efficiency of $992 = (3 \times 50) = 4.96$ users/cell/MHz is achievable. Similarly, for a cluster size of 3, 6.61 users/cell/MHz is achieved.

BURSTS, CHANNELS, DUPLEXING, AND FRAME STRUCTURE

Physical Channels

GSM is a fully digital system with a multiple-access architecture based on the narrowband frequency division multiple access, TDMA, and *frequency division duplexing* (FDD) technology. The carrier spacing is 200 kHz in GSM 900, *extended GSM* (EGSM), DCS 1800, and PCS 1900. A channel consists of a pair of 200-kHz frequency segments, one for uplink and one for downlink. The separation between uplink and downlink varies, depending on the GSM version. Table 2 shows the parameters of GSM channels. In EGSM, the original GSM 900 operating band is extended, and lower-power terminals and smaller serving areas (microcells) are specified. In all versions of GSM systems, a frequency channel is divided into eight time slots (0 to 7) per frame, allowing simultaneous use of the channel using time sharing. The duration of a GSM frame is 4.615 ms and therefore a time slot has a duration of 577 μ s.

Although the 25-MHz spectrum per direction for GSM 900 admits 125 200-kHz carriers, in order to allow for 100-kHz of guard bands at both edges of the spectrum, only 124 carriers are used.

Figure 4: Time division duplexing in GSM

Duplexing

In the communication via radio channel, the interference between uplink and downlink transmissions is avoided with one of two duplexing techniques—namely, frequency division duplexing and *time division duplexing* (TDD). Both modes are specified in the GSM standard. In the FDD mode, two filters called *duplexers* at the transceiver attenuate the operating frequency of the complementary functions. This keeps the transmitter's energy out of the receiver's input. Thus, a single common antenna could be used with such a filter system. This allows the use of the channel in full duplex mode. In TDD mode, on the other hand, different time slots are used for uplink and downlink; therefore, the channel operates in half-duplex mode in some sense. In GSM TDD mode, the uplink and downlink transmission takes place with an offset of three time slots. Figure 4 shows the uplink-downlink time-slot structure. The eight time slots numbered from 0 to 7 are assigned to eight different users.

Slot Formats

As already described, a time slot in GSM with duration contains 156.25 bits. GSM specifies five different time slot formats, or burst formats that are used for various functions: normal, synchronization, frequency correction, access, and dummy burst. Furthermore, these bursts are used in different logical channels based on the tasks.

1. The *normal burst* carries user information or network control information.
2. A *synchronization burst* performs time synchronization of the terminal operations with the base station.
3. The *frequency correction burst* synchronizes the terminal with the base station. During this burst, the BTS transmits a signal that has a frequency 67.7 kHz above that of the carrier.

Table 2: Channels in GSM Bands

System	Uplink (MHz)	Downlink (MHz)	Number of duplex channels	Uplink-downlink spacing (MHz)
GSM 900	890–915	935–960	125	45
EGSM	880–915	925–960	175	45
DCS 1800	1710–1785	1805–1880	375	95
PCS 1900	1850–1910	1930–1990	300	80

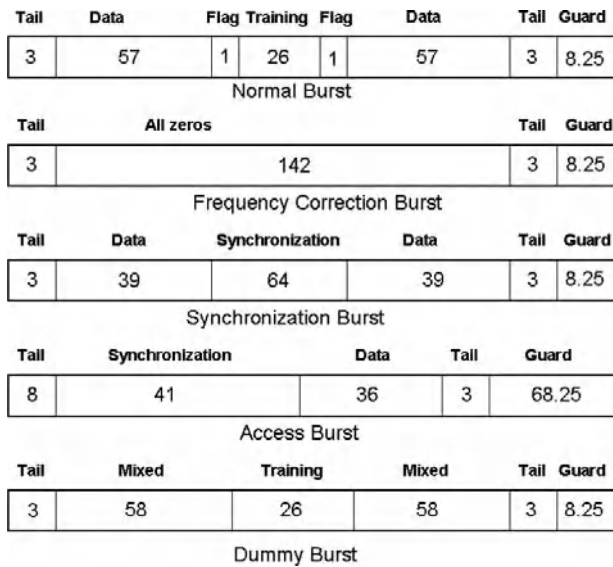

Figure 5: The GSM burst (time-slot) structure

4. An *access burst* initiates a dialog with the system through a signaling protocol.
5. The *dummy burst* carries no information and is transmitted by the BTS.

Figure 5 shows the format of each of these bursts with respect to the use of bits. All of the burst types have a tail field entirely of zero bits to indicate the start and end of the burst. These bits are also used by the adaptive equalizer. All of the burst types use the first three bits to indicate the start of a burst except for the access burst, which uses the first eight bits for this purpose. In all of the burst types, the last 8.25 bits are used for the guard field except for the access burst, which uses the last 68.25 bits for the guard field. The guard bits avoid overlaps between slots. The access burst is allocated a large guard to allow for uplink transmissions from different areas of a cell to arrive at the BTS within a time-slot duration. The guard field also allows the transmitter to turn off at the end of a time slot and to turn on at the start of the next. The three bits just before the guard bits are used for the ending tail field. The normal and the synchronization bursts have two data fields, one following the start tail field and another before the end tail field. These fields are fifty-seven and thirty-nine bits long, respectively, for the normal burst and the synchronization burst. The access burst includes one data field before the ending tail and is thirty-six bits. The data field in a normal burst may be used for user information or network control information. In other bursts, it is used for network control information. The normal burst includes a single bit flag just after the first data field and another single bit flag just before the second data field. These flags indicate whether the transmitted information is user information or network information. The training bits carry the training sequence used in adaptive equalization. As seen in Figure 5, this is used in normal burst and the dummy burst. The synchronization field present in the synchronization burst and the access burst contains a known bit pattern (synchronization sequence) to be used in time synchronization.

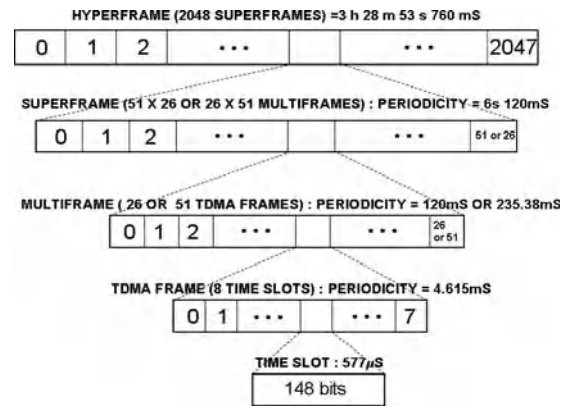

Figure 6: The GSM frame hierarchy

The Frame Hierarchy

In the frame hierarchy of GSM, the largest frame—namely, the *hyperframe*—has a duration of 3h, 28m, 53s, and 760 ms. Down the hierarchy, there are *superframes*, *multiframes*, *frames*, and *slots*. A hyperframe includes multiple superframes. There are two formats for superframes with fifty-one or twenty-six multiframes. Each multiframe in turn consists of multiple frames. Again, there are two formats for multiframes. Nevertheless, the duration of a superframe is 6s, 120ms in both formats. This is achieved by having twenty-six frames per superframe in the case of fifty-one multiframes or a superframe and vice versa. Each frame consists of eight time slots and therefore has a duration of 4.615 ms. The hierarchy and timing are shown in Figure 6.

Logical Channels

Several logical channels are defined in GSM. The definitions are based on the tasks. Figure 7 shows the categorizations and subcategorizations of these channels. There are two major types: (1) traffic channels used for speech and data and (2) signaling channels for control signaling. As seen in the figure, for speech there are full rate and half-rate traffic channels (TCH/F and TCH/H, respectively). There are three types of traffic channels with varying data rates. Numbers indicated are in kbits/s.

There are three groups of signaling channels: (1) broadcast, (2) common control, and (3) dedicated control channels. Broadcast channels and common control channels are one-way channels and occupy time slot 0 on standard broadcast carriers. The common control channels may also use slots 2, 4, and 6 of this carrier. Dedicated control channels are two-way channels and may use any time slot of the frame and of any carrier except slot 0 of the standard broadcast carrier.

Broadcast channels are of three types: (1) the *frequency correction channel* (FCCH), (2) the *synchronization channel* (SCH), and (3) the *broadcast control channel* (BCCH). The following are three common types: (1) the *paging channel* (PCH), (2) the *access grant channel* (AGCH), and (3) the *random-access channel* (RACH).

There are three types of dedicated control channels: (1) the *stand-alone dedicated control channel* (SDCCH),

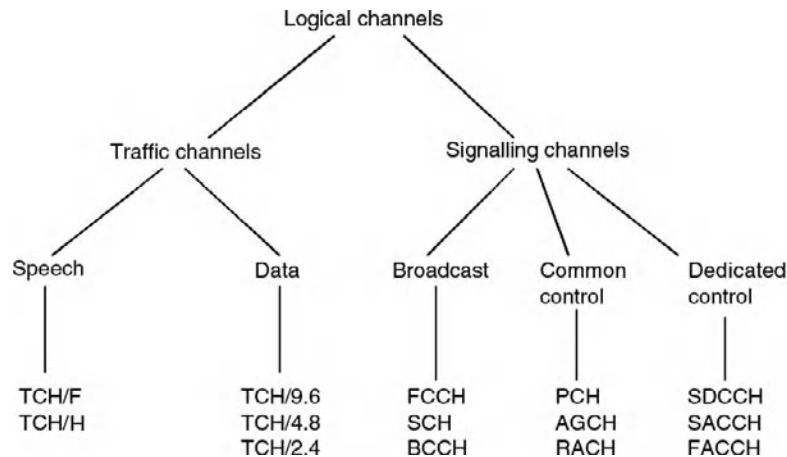

Figure 7: The logical channels in GSM

(2) the *slow associated control channel* (SACCH), and (3) the *fast associated control channel* (FACCH). These channels will be detailed later in this chapter. The logical channels are related to the frame hierarchy.

FUNCTIONS AND MESSAGES

In this section, we discuss different functions defined in the GSM standards and describe the related messages passed between different entities.

Call Management

Among the call management procedures are mobile initialization, location update, authentication, ciphering, mobile station termination, mobile station origination, handover, and call clearing. Mobile initialization procedure includes frequency synchronization, timing synchronization, and overhead information acquisition.

When a mobile terminal is switched on, the following sequence of events takes place. First, the terminal scans the available GSM RF channels and performs operations such as estimating signal strengths using several readings of power levels. Starting with the channel with the highest level, the terminal then searches for the frequency correction burst on the BCCH. When a burst is found, the terminal then synchronizes its local oscillator with the frequency reference of the base station transceiver. Once the frequency synchronization has been achieved, the terminal will search for the synchronization burst for the timing information present on the SCH. If it is not successful, it then moves to the channel with next highest signal level and repeats the process starting from the frequency synchronization procedure until it is successful. Once the time synchronization is achieved, the terminal moves to the BCCH to acquire overhead system information. If the BCCH information does not include the current BCCH number, then the terminal will restart the mobile initialization procedure. If successful in finding the information, the terminal will have acquired (from the BCCH and through the system information message present on the BCCH) information such as country code, network code, location area code, cell identity, adjacent cell list, BCCH location, and minimum received signal strength.

Next, the terminal checks to see if the acquired identification codes coincide with those in the SIM card. In a successful event, it will maintain the link and monitor the PCH. Otherwise, it will start a location update procedure. A location update procedure is carried out also in the event of moving into an area different from that currently registered or when there is no activity for a certain amount of time. Location reports are used in the paging procedure as well. The time span between location reports constitutes a system parameter whose value is indicated on the BCCH, varying in accordance with the network loading.

Mobile Station Termination

After the mobile initialization procedure, the terminal locks onto the PCH. It eventually detects a paging request message conveying its TMSI. This causes the terminal to access the RACH to transmit a channel request message. An immediate assignment with the SDCCH number is sent by the network on the AGCH. The terminal moves to SDCCH and then transmits a paging response message indicating that the response is to a paging. Next, an authentication procedure is carried out. The authentication procedure is described in “Authentication” below. If the authentication is successful, a ciphering procedure is accomplished. The base station then sends a setup message. The terminal responds with a call confirmed message followed by an alerting message to indicate that the subscriber is being alerted. At the subscriber’s call acceptance, the terminal sends a connect message and removes the alerting tone. The network responds with an assignment command message indicating the traffic channel number to be used for the conversation. The subscriber, still on the SDCCH, responds with an assignment acknowledgment message and moves to the traffic channel that has been assigned. The network confirms the acceptance of the call by the other party by means of a connect acknowledgment message on the FACCH of the assigned TCH. And the conversation proceeds on the TCH.

Mobile Station Origination

The terminal detects a user-originated call. It then accesses the RACH to send a channel request message.

An immediate assignment with the SD-CCH number is sent by the network on the AGCH. The terminal moves to this channel and transmits a paging response message indicating that the message is for call setup. The base station responds with an unnumbered acknowledgment message. As will be described below, an authentication procedure is carried out. If authentication is successful, then a ciphering procedure is performed. The terminal then sends a setup message. The base station responds with a call confirmed message followed by an alerting message in which case the terminal applies the ring-back tone. At the called party's call acceptance, the network sends an assignment command message informing the traffic channel number to be used for the conversation. The subscriber, still on the SDCCH, responds with an assignment acknowledgment message and moves to the traffic channel that has been assigned. The network confirms the acceptance of the call by the other party by means of a connect acknowledgment message on the FACCH of the assigned TCH. And the conversation proceeds on the TCH.

Handover

The handover process in a GSM is termed *mobile-assisted handover* because the mobile terminal plays a major role in the process. Using the traffic channel, the mobile monitors the signal levels on the channel used by the terminal itself as well as the channels used within a cluster of six cells, including the cell in which the terminal is located. The measurements are then reported to the base station on an SACCH. Concerning the control of the process, handovers may occur within the same BTS, between BTSs controlled by the same BSC, between different BSCs controlled by the same MSC, between different BSCs controlled by different MSCs, or between different BSCs controlled by different MSCs belonging to different PLMNs.

Furthermore, there are two modes of handovers in GSM: synchronous and asynchronous. In the *synchronous* mode, the origin cell and the destination cell are synchronized. By measuring the time difference between their respective time slots, the mobile may compute the timing advance by itself. This is used to adjust its transmissions on the new channel, therefore speeding up the handover process. In the *asynchronous* mode, the origin cell and the destination cell are not synchronized. In this case, the timing advance must be acquired by means of a procedure involving the terminal and the new BTS, as follows. The mobile terminal sends a series of access bursts with a zero timing advance through several handover access messages. The BTS then computes the required timing advance using the messages round-trip time delay. On the average, the handover processing time in the asynchronous mode is twice as long as that of the synchronous mode (200 ms versus 100 ms).

A simple asynchronous handover procedure occurring between BTSs of the same BSC is described. While in conversation on a TCH, the terminal monitors the signal levels of several channels. These measurements are reported to the base station on a periodic basis by means of the measurement report message running on the SACCH. Whenever suitable, the base sends a handover command message on the FACCH, indicating that a handover is

to take place. The number of the new TCH is included within the message. The terminal then moves to this new channel and sends a series of handover access messages so that the base may compute the timing advance to be transmitted to the terminal. This is done in the physical information message transmitted to the terminal on the FACCH. The timing adjustment is carried out, and the terminal responds with a handover complete message.

Call Clearing

The call clearing process may be initiated either by the network or by the mobile. In either case, the channel used for the exchange of information is the BCCH. Assuming that the network initiates the clearing, the base sends a disconnect message to the terminal. The terminal responds with a release message. The base replies with a release complete message. If the terminal initiates the clearing, then the same messages flow in the opposite direction.

Mobility and Roaming Location-Based Services

Regional Roaming

Regional roaming refers to the ability to move from one region to another region inside national coverage of the mobile operator. This is only allowed if a mobile operator grants a user this right in the user's subscription. In the first ages of GSM, operators made commercial offers restricted to a region (sometimes to a town). Because of GSM's widespread success and the decrease in cost usage, regional roaming is no longer offered to clients unless in wide geographical areas such as large countries (e.g., the United States, Russia, and India). In this last case, regional roaming is more related to national roaming.

National Roaming

National roaming refers to the ability to move from a mobile operator to another mobile operator in the same country. As an example, consider subscribers of T-Mobile US. They would have national roaming rights if they were allowed to roam inside Cingular's wireless coverage. For commercial and license reasons, this type of roaming is not allowed unless under specific circumstances and under regulator scrutiny. As an example, the first 3G operators (like Hutchinson subsidiaries) had little coverage compared to 2G operators. For fair competition, regulators (e.g., in the United Kingdom and in Italy) granted rights for these operators to make national roaming agreements with one of the 2G operators. These agreements were limited in space to geographical areas and in time.

International Roaming

International roaming refers to the ability to move onto other foreign mobile operators from a national subscription. By now, as stated before, *roaming* now commonly refers to international roaming.

Security

The known problems in GSM's analog counterparts included phone fraud by cloning, making calls at an owner's

expense, and intercepting phone calls. The GSM system includes strong authentication between MS and MSC. Furthermore, there is strong data encryption for transmission through wireless channel from MS and BTS. The GSM specifications were developed in secrecy and were distributed on a need-to-know basis to the manufacturers and network operators. The security algorithms for GSM were developed by the *Security Algorithm Group of Experts* (SAGE). Although the specifications were supposed to be closed to the public, information on the algorithms leaked in the mid-1990. SAGE's security mechanisms for GSM are implemented in three different elements—namely, the SIM, ME, and the network. The SIM contains the IMSI, K_i , algorithm A8 (for cipher key generation), algorithm A3 (for authentication), and the PIN. The ME contains the ciphering algorithm A5. The three algorithms A3, A5, and A8 are present in the network. The AuC contains a database of identification and authentication information for subscribers. It includes the IMSI and K_i of each subscriber as well as the algorithms A3 and A8.

The elements of GSM security are subscriber identity authentication, user and signaling data confidentiality, and subscriber identity confidentiality.

Authentication

The IMSI and the authentication key, K_i constitute the a subscriber's identity credentials. These bits of information are never transmitted over the radio channels. Instead the TMSI is used by the MS to identify itself to the network. The authentication is performed with a challenge-response mechanism that avoids sending the key K_i over the air.

The authentication procedure starts when the network sends an authentication request message to the terminal; the message conveys a 128-bit RAND. The terminal uses the RAND, the secret key K_i stored at SIM, and the encryption algorithm (referred to as A3) to compute a 32-bit number, which is referred to as a *signed response* (SRES). The 64-bit ciphering key, K_c also is computed using another encryption algorithm, referred to as A8. The K_c parameter is later used in the ciphering procedure. After these computations, the terminal responds with an authentication response message, which contains the SRES. The network uses the same parameters and the same algorithm to compute another SRES. The terminal SRES and the network SRES are then compared with each other. If a match occurs, the network then accepts the user as an authorized subscriber. Otherwise, the authentication is rejected.

The TMSI update process is as follows. The network knows the association between the TMSI and IMSI. The MS identifies itself to the network by sending the TMSI. Following the authentication process, the new TMSI generated by the network is sent to the MS encrypted with the cipher key K_c . The MS replaces the old TMSI with the new one.

Ciphering

Ciphering (or *encryption*) is usually required for user transactions over the RF link after authentication has been successful. The network transmits a ciphering mode message to the terminal that indicates whether encryption

is to be applied. If ciphering is to be performed, the secret key K_c (64 bits), which was generated previously in the authentication procedure, the frame number (22 bits), and an encryption algorithm (referred to as A5) are used to compute a 114-bit encryption mask. This mask is modulo-2 added to the $2 \times 57 = 114$ bits of the data fields in the bursts. Deciphering is obtained at the base station by performing the same procedure. The terminal answers with a ciphering mode acknowledgment message. Note that the ciphering to be used is continuously changing (on a frame-by-frame basis) because it depends on the current frame number. Note that the key K_c is temporary.

Attacks on GSM Security

Although the security algorithms were originally kept secret, they later became public knowledge. The security research community now widely accepts that keeping the algorithms secret is not the way to achieve security. Communication between BS and BSC is often established with microwave links, which are not encrypted in general. This is one of the vulnerabilities in GSM networks. Some operators implement lower-layer bulk encryption for protection against this vulnerability. Another known vulnerability exists in the COMP128 algorithm that combines A3 and A8 into a single algorithm and generates both SRES and the key K_c on one run. COMP128 takes the 128-bit RAND and the 128-bit K_i as input and generates a 128-bit output of which the first thirty-two bits are SRES and the last fifty-four bits are the session key, K_c . The session key is appended by zeros to produce a 64-bit key. Nevertheless, the effective key length is fifty-four bits. In 1998, the Smart Card Developer Association and the Internet Security, Applications, Authentication and Cryptography security research group showed that it is possible to retrieve the secret key K_i with 160,000 chosen RAND-SRES pairs. With faster SIM, this could be achieved in approximately 2.5 hours. It is also possible to use a false BS to send the RAND over the air interface.

Another possible attack uses the side channels such as those used in the computation of power consumption and timing operations. With physical access to the SIM card, it is possible to extract secret key K_i by a partition attack approach developed by IBM researchers.

Messages

The signaling channels, with the exception of FCCH, RACH, and SCH, use the *link access protocol on the Dm channel* (LAPDm) format to transmit information. The LAPDm protocol in the mobile network is equivalent to the LAPD protocol in the fixed network. The messages are transmitted in segments of 184 bits. In general, the messages fit into a single segment and the 184 bits of raw information are processed to yield 456 bits. These 456 bits are then transmitted through four time slots. Apart from the length indicator field, which appears in every message, the presence of the other fields will depend on the message itself. For example, there may be messages with zero length; in this case, with the exception of the eight-bit length indicator field, all of the other fields (176 bits) are filled with 1's.

Six of the bits in the length indicator field denote the number of octets in the variable length information field. Another bit in the length indicator field determines whether the current message segment is the final segment in the corresponding message. The address field contains the following fields: One bit indicates whether the message is a command or a response; three bits indicate the current version of the GSM protocol; one bit is an extension of the address (set to 0 in the initial version of GSM); and three bits indicate network management messages or SMS messages. The control field contains three bits to indicate the sequence number of the current message and another three bits to indicate the sequence number of the last message received by the entity that is sending the current message. In case the complete message encompasses fewer than 184 bits, the fill field is stuffed with 1's.

Several network management messages are specified in GSM. According to their specific functions, the messages can be of three types: *supervisory* (S), *unnumbered* (U), or *information* (I). The S and U messages precede or follow the I messages to control the flow of messages between terminals and base stations. The I messages perform the main tasks concerning network management. An S message may request (re)transmission or may suspend transmission of I messages. An U message may initiate or terminate a transfer of I messages, or it may confirm a command. The S and U messages are layer 2 messages and, more specifically, *data-link control* (DLC) messages. The I messages are layer 3 messages. More specifically, they carry out the network management operations such as *radio resources management* (RRM), *mobility management* (MM), and *call management* (CM). The RRM messages involve interactions between mobile station, base station, and mobile switching center. The MM and CM messages use the base station as a relay node between mobile stations and the MSC, where they are effectively treated.

The next subsections summarize the main GSM messages.

Data-Link Control Messages

The main DLC messages and their respective purposes are listed below.

- Set asynchronous balanced mode: This is a U command message that initiates a transfer of I messages.
- Disconnect: This U command message terminates a transfer of I messages.
- Unnumbered acknowledgment: This U response message confirms a command.
- Receive ready: This S command or S response message requests transmission of an I message.
- Receive not ready: This S command or S response message requests retransmission of an I message.
- Reject: This S command or S response message suspends transmission of I messages.

Radio Resources Management Messages

The main RRM messages and their respective purposes are listed below.

- Sync channel information: This is a downlink message running on the SCH. It conveys the base station identifier and the frame number, the latter allowing the terminal to achieve time synchronization.
- System information: This downlink message running on the BCCH contains the location area identifier, the number of the physical channel carrying signaling information, the parameters of the random access protocols, and the radio frequency carriers active in the neighboring cells.
- System information: This downlink message running on the SACCH provides local system information to those active terminals that are moving away from the cell where the call was originated.
- Channel request: This uplink message running on the RACH is used to respond to a page, to set up a call, to update the location, to attach the IMSI, and to detach the IMSI.
- Paging request: This downlink message running on the PCH sets up a call to a terminal.
- Immediate assignment: This downlink message running on the AGCH assigns an SDCCH to a terminal at the setup procedure as a result of a channel request message.
- Immediate assignment extended: This downlink message running on the AGCH assigns two terminals to two different physical channels.
- Immediate assignment reject: This downlink message running on the AFCH is utilized as a response to channel request messages from as many as five terminals when the system is not able to provide these terminals with dedicated channels.
- Assignment command: This downlink message running on the SDCCH is used at the end of the setup call process to move the terminal to a TCH.
- Additional assignment: This downlink message running on the FACCH assigns another TCH to a terminal already operating on a TCH.
- Paging response: This uplink message running on the SDCCH is used to respond to a page with the aim of identifying the terminal and causing initiation of the authentication procedure.
- Measurement report: This uplink message running on the SACCH indicates the signal level of the terminal and the signal quality of the active physical channel and of the channels of the surrounding cells for intracell or intercell handover purposes.
- Handover command: This downlink message running on the FACCH is used to move a call from one physical channel to another physical channel. It is also used by the terminal to adjust its timing advance.
- Handover access: This uplink message running on the TCH provides the base station with the necessary information so that the base can instruct the terminal on the timing adjustment needed in a handover process.
- Physical information: This downlink message running on the FACCH transmits the timing adjustment required by the terminal in a handover process.
- Handover complete: This uplink message running on the FACCH is utilized after the terminal has adjusted its

transmission time within the newly assigned physical channel.

- **Ciphering mode:** This downlink message running on the FACCH indicates whether user information is to be encrypted.
- **Channel release:** This downlink message running on the FACCH informs the terminal that a given channel is to be released.
- **Frequency redefinition:** This downlink message running on both the SACCH and the FACCH informs the terminal about the new hopping pattern to be used.
- **Classmark change:** This uplink message running on both the SACCH and the FACCH informs the network about the terminal's new class of transmission power. This message occurs, for example, when a phone is plugged in or removed from an external apparatus with high power.
- **Channel mode modify:** This downlink message running on the FACCH commands the terminal to change from one channel mode (speech or data) to another. The channel mode defines the specific source coder (for speech) or the data speed (for data).
- **RR status:** This two-way message running on both the FACCH and the SACCH reports the error conditions of the *radio resource* (RR).

Call Management Messages

The main CM messages and their respective purposes are listed below.

- **Setup:** This two-way message running on the SDCCH is used to initiate a call.
- **Emergency setup:** This uplink message running on the SDCCH is used to initiate a call.
- **Call proceeding:** This downlink message running on the SDCCH is used as a response to a setup message.
- **Progress:** This downlink message running on the SDCCH informs the calling party, through an audible tone, that the call is being transferred to a different network (e.g., from a public to a private one).
- **Call confirmed:** This uplink message running on the SDCCH is used as a response to a setup message.
- **Alerting:** This two-way message running on the SDCCH indicates to the calling party that the called party is being alerted.
- **Connect:** This two-way message running on the SDCCH indicates that the call is being accepted.
- **Start DTMF:** This uplink message running on the FACCH is used to indicate that a button of the phone keypad has been pressed. This causes the network to send a dual-tone multiple frequency to the terminal.
- **Stop DTMF:** This uplink message running on the FACCH indicates that a button of the phone keypad has been released. This causes the network to turn off a dual-tone multiple frequency.
- **Modify:** This two-way message running on the FACCH indicates that the nature of the transmission is being modified (e.g., from speech to facsimile).

- **User information:** This two-way message running on the FACCH is used, for example, to carry user-to-user information as part of GSM supplementary services.
- **Disconnect, release, release complete:** This two-way message running on the FACCH is used to end a call. For example, if the terminal is concluding a call, it sends a disconnect message to the network, which responds with a release message; this causes the terminal to send a release complete message to the network. The same sequence of messages flow in the opposite direction if the other party terminates the call.
- **Disconnect:** This two-way message running on the FACCH indicates that a call is terminating.
- **Release:** This two-way message running on the FACCH is used as a response to a disconnect message.
- **Release complete:** This two-way message running on the FACCH is used as a response to a release message.
- **Status:** This two-way message running on the FACCH is used as a response to a status enquiry message to describe error conditions.
- **Status enquiry:** This two-way message running on the FACCH causes the network element (either the terminal or the base) to respond with a status message.
- **Congestion control:** This two-way message running on the FACCH initiates a flow control procedure, in which case the flow of call management messages is retarded.

The CM messages occur at different stages of a call. At the beginning of a call, the following messages run on the SDCCH: setup, emergency setup, call proceeding, progress, call confirm, alerting, and connect.

During a call, the following messages run on the FACCH of the assigned channel: start DTMF, stop DTMF, modify, and user information.

At the end of a call, the following messages run on the FACCH of the assigned channel: disconnect, release, and release complete.

During abnormal conditions, the following messages run on the FACCH of the assigned channel: status, status enquiry, and congestion control.

Mobility Management Messages

The MM messages travel on the SDCCH. The MM messages and their respective purposes are listed below.

- **Authentication request:** This downlink message sends a 128-bit RAND to the terminal, which, by means of an encryption algorithm, computes a 32-bit number to be sent to and checked at the base.
- **Authentication response:** This uplink message is used as a response to an authentication request message, conveying the 32-bit number generated from the encryption algorithm.
- **Authentication reject:** This downlink message aborts the communication between the terminal and the network as a result of an unsuccessful authentication.
- **Identity request:** This downlink message is used to request any of the three identifiers: the IMSI (stored on the

SIM), the IMEI (stored in the terminal), and the TMSI (assigned by the network to a visiting terminal).

- Identity response: This uplink message is used as a response to the identity request message.
- TMSI reallocation command: This downlink message assigns a new TMSI to the terminal.
- Location updating request: This uplink message is used by the terminal to register its location.
- Location updating accept: This downlink message is used to accept a location registration.
- Location updating reject: This downlink message is used to reject a location registration. A location updating may be rejected in any of the following events: unknown subscriber, unknown location area, roaming not allowed, or system failure.
- IMSI detach indication: This uplink message cancels the terminal registration when the terminal is switched off.
- CM service request: This uplink message initiates an MM operation. As a consequence, one or more MM messages will follow.
- CM reestablishment request: This uplink message reinitiates an MM operation that has been interrupted.
- MM status: This two-way message reports error conditions.

RESOURCES

This section provides information on various resources related to GSM. These include standards organizations and forums. The inception of GSM in the early 1980s started with the Conference of European Posts and Telegraphs, which later evolved into the European Telecommunications Standards Institute. Currently, ETSI supports GSM and UMTS standardization activities. The International Telecommunications Union's Telecommunication (ITU-T) and its Standardization Sector is another organization that is coordinating cellular standardization activities. The ITU's Development Sector has contributed to promoting GSM. The Global Mobile Suppliers Association is another contributor to the development of GSM standards. The GSM Association (GSMA), is a consortium of second- and third-generation mobile operators, manufacturers, and suppliers. GSMA promotes triband GSM networks and equipment. The GSM Roaming Forum is an organization that promotes platforms and mobile equipment for seamless roaming across national boundaries and frequency bands. The GSM Alliance, the Mobile Data Association, and the Mobile Data Initiative Next-Generation Consortium are among other players.

CONCLUSION

GSM has emerged as a digital solution to the incompatible analog air interfaces of the differing cellular networks operating in Europe. Among the set of ambitious targets to be pursued, full roaming was indeed an extremely important one. In addition, a large number of open interfaces have been specified within the GSM architecture. Open interfaces favor market competition with operators able to choose equipment from different vendors. GSM

was the first system to stimulate the incorporation of the personal communication services philosophy into a cellular network. These and other innovative features rendered GSM networks, either in the original GSM conception or as an evolution of it, a highly successful project with worldwide acceptance. GSM systems are found operating in frequency bands around 900 MHz (GSM 900), 1.8 GHz (GSM 1800), and 1.9 GHz (GSM 1900). A new revision of the GSM specifications defines an EGSM that extends the original GSM 900 operation band and stipulates lower power terminals and smaller serving areas.

GLOSSARY

Access Grant Channel (AGCH): A downlink channel (base to mobile) used by a base station to tell the mobile station which dedicated control channel to use.

Authentication Center (AuC): A function to authenticate each subscriber identification module.

Base Station Controller (BSC): The functional entity that is responsible for radio resource allocation to a mobile station, frequency administration, and handover between base transceiver station.

Base Station Subsystem (BSS): A term given to a base station controller and the base transceiver station associated with it.

Base Transceiver Station (BTS): The equipment that facilitates the wireless communication between user equipments and the network.

Bearer Service (BS): Typically, data transmission instead of voice. Fax and short message services are examples.

Broadcast Control Channel (BCCH): The channel by which the mobile station is informed of the specific system parameters needed to identify the network or gain access.

Burst: The signal transmitted during a GSM time slot.

Conference of European Posts and Telegraphs (CEPT): The main European body for telecommunications standardization.

Digital Cellular System 1800 (DCS 1800): The U.K. Department of Trade and Industry defined *personal communications network* to consist of GSM operating in the 1.8-GHz band.

Discontinuous Transmission (DTx): A method that takes advantage of the silences in voice to increase the utilization of the channels.

Equipment Identity Register (EIR): Database employed within mobile networks to hold records of mobiles.

European Telecommunications Standards Institute (ETSI): An independent, not-for-profit, standardization organization of the telecommunications industry in Europe.

Frequency Correction Channel (FCCH): The logical channel in GSM systems used to transmit a frequency correction data burst of all zeros.

Frequency Division Duplexing (FDD): Radio technology using a paired spectrum for two-way communication.

Frequency Hopping (FH): Method of transmitting radio signals by rapidly switching a carrier among many frequency channels.

Home Location Register (HLR): Central database that contains details of each mobile.

International Mobile Equipment Identifier (IMEI): A unique fifteen-digit number that serves as the serial number of the GSM handset.

International Mobile Subscriber Identity (IMSI): Unique number associated with all GSM and universal mobile telecommunications system (UMTS) network mobile phone users.

Link Access Protocol for the ISDN D-channel (LAPD): Protocol providing error-free transmission between the BSC and MSC.

Mobile-Assisted Handover: Handoff technique involving feedback from the mobile station as part of the handoff process.

Mobile Station (MS): All user equipment and software needed for communication with a wireless telephone network.

Mobile Station Subsystem (MSS): Section of a traditional cellular telephone network responsible for handling traffic and signaling between a mobile phone and the network switching subsystem.

Mobile Subscriber ISDN (MSISDN): Telephone number of a mobile subscriber.

Mobile Switching Center (MSC): An ISDN switch coordinating and setting up calls to and from mobile stations.

Network and Switching Subsystem (NSS): Component of a GSM system that manages the communications between mobile phones and the public switched telephone network.

Operation and Support Subsystem (OSS): Functional entity from which the network operator monitors and controls the system.

Paging Channel (PCH): Base to mobile channel used to alert a mobile to a call originating from the network.

Personal Communication System 1900 (PCS 1900): Digital network working on a frequency of 1900 MHz; used in the United States and Canada.

Personal Identification Number (PIN): Four-digit secret number built into the subscriber identity module that should be entered to enable mobile use.

PIN Unblocking Key (PUK): Eight-digit personal unblocking key required when a wrong personal identification number is entered three times.

Random-Access Channel (RACH): Channel used by mobiles to gain access to the system when first attaching to it.

Security Algorithm Group of Experts (SAGE): With ETSI approval, carries out work for other organizations (e.g., for GSM by request of the GSM MOU).

Short Message Service (SMS): Often called *text messaging*; a means of sending short messages to and from mobile phones.

Slow Associated Control Channel (SACCH): Signaling channel that provides a relatively slow signaling connection.

Stand-Alone Dedicated Control Channel (SDCCH): This channel is used in the GSM system to provide a reliable connection for signaling and SMS.

Subscriber Identity Module (SIM): Smart card that provides mobile equipment with an identity.

Supplementary Services (SS): Services that complement and support telephony and data services such as call forwarding, call holding, and call waiting.

Synchronization Channel (SCH): Supplies the mobile station with the training sequence needed for the demodulation of information from the base station.

Teleservices (TS): Includes videotex, teletex, and advanced message handling.

Temporary Mobile Subscriber Identity (TMSI): Issued by the network and may be changed periodically (i.e., during handoffs) for additional security.

Terminal Adapter (TA): Part of the mobile station handling authentication requests from the GSM network.

Terminal Equipment (TE): Equipment in mobile that handles various functions such as control signaling and signal processing.

Time Division Duplexing (TDD): Radio technology for use in unpaired spectrum by applying time division multiplexing to separate outward and return signals.

Time Division Multiple Access (TDMA): Technique for multiplexing multiple users onto a single channel on a single carrier by splitting the carrier into time slots and allocating these on an as-needed basis.

Traffic Channel (TCH): Channels reserved for user data.

Visitor Location Register (VLR): Contains relevant data of all mobiles currently located in a serving mobile switching center.

Voice Activity Detector (VAD): Procedure to determine the presence or absence of speech.

INTRODUCTION

The GSM cellular system, described in the chapter entitled "Global System for Mobile Communications," was designed to support both digital voice traffic and user data traffic to and from mobile subscribers (Mouly and Pautet 1992; Haug 1994; GSM World n.d.). However, the data services provided by the initial GSM system are *circuit-switched services* in which, when a user invokes a data service, a data traffic channel is assigned and held in place until the call is terminated. This is analogous to using a dialup modem in the public telephone network. The user data rates for GSM circuit-switched data were limited to a maximum of 19.6 kbits/s (Heine 1999). The GSM system does include provisions for wireless access to public switched packet data networks (PSPDNs); however, this form of access simply carries packet-formatted data traffic over a circuit-switched traffic channel for the full duration of a call connection. In cases of discontinuous traffic, such as Internet and Web access, circuit-switched access can result in very inefficient use of wireless spectrum. Thus, the use of true *packet-switched data service* on the GSM radio channels can provide better utilization of wireless network capacity.

Another issue for the evolution of GSM data services was the customer demand for substantially higher data rates than could be supported in the early GSM networks. This led to the specification in Phase 2+ of the GSM development of *high-speed circuit-switched data* (HSCSD), in which a mobile station can access up to four time slots in each *time-division multiple access* (TDMA) frame, thereby achieving uplink data rates up to 57.6 kbits/sec (ETSI 1997a). Another important Phase 2+ element in the evolution of data services in GSM is general packet radio service (GPRS), which is the subject of this chapter. The GSM designation Phase 2+ denotes the fact that these services are built upon the Phase 2 GSM architecture while providing some of the capabilities envisioned for a subsequent

third generation (3G) of wireless systems. A section near the end of this chapter provides further discussion of 3G objectives.

Stated briefly, GPRS overlays true packet-switched data service onto a GSM network in a way that maintains strict separation between radio subsystem and the network system, with the advantage that no modifications to *mobile switching centers* (MSCs) are required (Steele, Lee, and Gould 2001). GPRS provisioning does require some enhancements and modifications to GSM infrastructure and mobile stations (MSs). In GPRS, the allocation of the eight time slots on one radio frequency (RF) channel is flexible, and various combinations of uplink and downlink time slots can be assigned depending upon the capabilities of the MS, the customer's service subscription, and the number of channels dedicated by the network operator to packet data service. The capacity of an underlying GSM service network can be shared dynamically between circuit-switched and packet data services, according to observed traffic demands. The theoretical upper limit on GPRS data rate is 171.2 kb/s, achieved by assigning all eight time slots in a GSM radio channel to a single user (Halonon, Romero, and Melero 2003). However, as a practical matter, GPRS mobile terminals operate at rates in the range of 30 to 80 kilobits/sec, using at most four time slots in one direction. As a related point, it is important to note that not all of the capabilities defined in the GPRS specifications have been implemented by equipment manufacturers and network operators.

Before discussing the details of GPRS, it is useful to review the differences between circuit-switched and packet-switched data services.

Circuit-Switched versus Packet-Switched Data Service

The key characteristic of GPRS is that it provides packet-switched data service rather than circuit-switched data

service, and this technique makes much more efficient use of the available capacity of the cellular network. This efficiency improvement comes from the fact that most data transfers are interactive and occur in a bursty fashion. Typical data transfers occur in short bundles, interspersed with longer intervals when there is little or no activity. The original GSM specification was developed to support primarily voice services, in which an end-to-end circuit connection is set up through the network and stays in place for the full duration of the call session. This is known as a circuit-switched service, and the services of the original GSM system provided exactly the same form of connection for data and fax transmissions, much like support of dialup modems and fax machines in the public switched telephone network (PSTN). Given the bursty nature of typical data transfers, the circuit-switched mode of service does not make the most efficient use of transmission capacity in the network.

To provide more efficient use of transmission resources, the overall capacity can be shared among multiple users. To achieve this the data stream to be transmitted is segmented into packets, and tags are inserted into the packets to provide destination addressing and other information. When one user's packet has been transmitted, the channel is made available for another user's packets. Packets from multiple sources can then be interspersed and transmitted over the channel. As it is unlikely that the data bursts for different users will occur all at the same time, by sharing the overall resource in this manner, the channel—or combined channels—can be used far more efficiently. This approach is known as *packet switching* (Tanenbaum 2003), and it is at the core of the GPRS design. The chapters entitled “Circuit Switching” and “Packet Switching” in this handbook deal with these switching technologies in detail.

Readers familiar with Internet technology (see the chapter entitled “Internet Fundamentals”) know that traffic is relayed across the Internet by way of *routers*, which function as packet-switching nodes. Though the user may typically access the Internet by way of a circuit-switched PSTN connection to an Internet service provider (ISP), the user's message stream is then handled as data and transported across the network in segments called Internet protocol (IP) *datagrams*—the datagrams being directed individually by the network routers. In fact, given the widespread use of the Internet, the reader will appreciate that data traffic carried over public networks today is predominantly packet oriented. Our later discussion of the GPRS network architecture will explain how GPRS separates the mobile user's data traffic from voice traffic, transporting the data using packet switching and the digital voice traffic using circuit switching in the underlying GSM network.

Evolution of Cellular Data Services

Data support over first-generation (1G) wireless networks began with the use of modems and facsimile terminals over advanced mobile phone service (AMPS) circuit-switched analog cellular telephone channels (DeRose 1999). In this form of data communication, the mobile user simply accessed a cellular channel just as he would in making an ordinary voice call over the cellular network. The customer attached a cellular modem—much like a dialup wireline

modem, but designed to operate on the AMPS radio interface—to a data terminal, a facsimile device, or a laptop computer. In this form of data communication, the cellular network was not actually providing a data service but simply a voice link over which the data modem or fax terminal could interoperate with a corresponding data modem or fax terminal in the office or service center (Pahlavan and Levesque 1995). Typical users of this mode of data communication included service technicians, real estate agents, traveling salespeople, and public safety personnel.

In another early form of mobile data service, the mobile subscriber used a portable modem or fax terminal as already described but accessed a modem installed by the cellular service provider as part of a *modem pool*, which was connected to the MSC. The user dialed into the modem pool using dedicated telephone numbers. The modem pool sometimes provided the customer with a choice of several standard modem types (Muller 1995). The call connection from the modem pool to the office or service center might be supported by any of a number of public packet data networks (PDNs), such as X.25 networks. Here, the cellular operator provided a special service in the form of modem pool access, and this service typically carried a higher tariff than did standard cellular voice service, due to the operator's added investment in the modem pools. In this form of service, however, the user in the office or service center did not require a modem but instead had a direct digital data connection to a desktop or host computer.

Each of the early types of wireless data communication just described was in effect an appliqué onto an underlying analog cellular telephone service and, therefore, suffered limitations imposed by the characteristics of the underlying voice-circuit connection. That is, the cellular segment of the call connection was a circuit-mode service, which might have been cost effective if the user needed to send long file transfers or fax transmissions, but relatively costly if only short messages were to be transferred. This is because the subscriber was being charged for a connection that remained in place throughout the duration of the communication session, even when only intermittent short message exchanges were needed.

The need for systems capable of providing more cost-effective communication of relatively short message exchanges led to the development of wireless packet-switched systems, including the first cellular packet data system: *cellular digital packet data* (CDPD). CDPD, developed by IBM in collaboration with the major cellular network carriers, allowed any cellular carrier owning a license for AMPS service to implement a cellular data service without need for further licensing (Muller 1995; Pahlavan and Levesque 1995). The basic concept of the CDPD system was to provide packet data service on a noninterfering basis along with the existing analog cellular voice service using the same 30 kHz radio channels. This was accomplished by devoting one or a few AMPS channels in each cell site to the transmission of packet-formatted data at data rates up to 19.2 kbits/sec.

The provision of CDPD service in an existing AMPS service network did not require modification of any of the AMPS network elements but did require the addition of *mobile data base stations* (MDBSs) and packet-switching equipment. The MDBS implements the functions needed

to support communication with the mobile user terminals, including modulation and demodulation of traffic data bits and support of the multiple-access protocol, over the RF channels reserved for CDPD traffic. The MDBSs are physically located at the service provider's cell sites, and each MDBS in effect relays mobile user data traffic between the mobile device and a key CDPD network element called a *mobile data intermediate system* (MD-IS). The MD-IS is responsible for most of the mobility management functions in the CDPD service network, tracking the current access point (an MDBS) for each mobile device active within the network. On its network side, the MD-IS serves as a routing node, communicating with outside packet data networks using standard packet-networking protocols. In a CDPD service network, the MD-IS is physically located at the MSC, which provides connections for analog voice traffic to and from the PSTN. Thus, in CDPD, we see data traffic being separated from voice traffic at the MSC level of the network architecture. Later, we will see a somewhat different configuration in the GPRS network architecture.

For a number of reasons, CDPD has not been successful in the marketplace and has been supplanted by data services designed into the second-generation (2G) cellular systems, as well as by GPRS, the subject of this chapter.

Data Services in GSM Networks

The first phase of the GSM specification, adopted in 1987, provided basic data transfer capabilities for the support of circuit-oriented data services, with maximum data rate initially limited to 9.6 kbits/s on one time slot in an eight-slot radio channel. During the development of the GSM specifications and the early deployment of GSM services, the customer demand for mobile access to the Internet had not been envisioned, and thus work was started on more advanced forms of data service. GSM Phase 2+, in Release '96, specified HSCSD, which significantly increased achievable data rates in the GSM system (ETSI 1997a). The maximum radio interface bit rate of an HSCSD service with 14.4 kbits/s channel coding is 115.2 kbits/sec, that is, up to eight times the bit rate of the single-slot full-rate traffic channel. In practice, the maximum data rate is limited to 64 kbits/sec owing to limitations in the GSM network (Hakaste, Nikula, and Hamiti 2003). Further evolution of cellular data services includes *enhanced data for global evolution* (EDGE), which builds upon the GPRS architecture, and other improved data services envisioned for the universal mobile telecommunications system (UMTS; 3rd-Generation Partnership Project [3GPP] n.d.). More is said about the future evolution near the end of the chapter.

From its inception, the GSM specification included short message service (SMS) in addition to the data transport services summarized earlier. SMS is a bidirectional service for transferring short (up to 160 bytes) alphanumeric messages with a store-and-forward protocol. Although SMS was conceived initially as supporting incoming-message alerts and perhaps some telemetry applications, users and service providers soon recognized the potential usefulness of SMS for text messaging, which has become very popular. In addition to point-to-point messaging, SMS also provides a cell-broadcast mode for distributing messages such

as traffic reports and news updates. SMS messages can be stored in the subscriber identity module (SIM) card of a GSM mobile phone for later retrieval. The great popularity of SMS service led (in 2.5G) to the specification of GPRS in GSM and to packet data service in the CDMA cellular system as well (Brasche and Walke 1997; Cai and Goodman 1997; Bates 2002).

Mobile messaging has now evolved beyond SMS text messaging with the introduction of multimedia messaging service (MMS), which allows delivery of personalized multimedia content such as images, audio, text, and video, as well as combinations of these.

Soon after the first GSM networks became operational in the early 1990s and customers gained experience with the GSM data services, it became evident that the circuit-switched bearer services were not particularly well suited for certain types of applications in which data traffic was discontinuous. The circuit-switched data services, although satisfactory for long file transfers, were not cost effective for the customer using the service for connections to the Internet or corporate networks, applications of growing importance in the business world. Similarly, from the service provider's perspective, the use of circuit-switched connections for carrying packet-formatted traffic did not make efficient use of cellular network capacity. At the same time, customer demand for higher-rate data grew steadily as new software applications for mobile users entered the marketplace. The development of GPRS, begun in 1994 as part of the GSM Phase 2+ specification, was an important step toward satisfying the evolving needs of mobile customers and cellular service providers as well. The primary GPRS specifications were approved by 1997.

The GPRS system brings packet-switched data services to the existing GSM system, providing the customer many advantages not afforded by the earlier GSM circuit-switched data services. In the GPRS system, mobile users can access public data networks directly using their standard protocol addresses, such as IP or X.25. The GPRS mobile station can use between one and eight traffic channels over the radio link. Depending on the MS capabilities, those channels are dynamically allocated to the MS when there are packets to be sent or received. In the GPRS network, uplink and downlink channels are reserved separately, making it possible to have MSs with various uplink and downlink capabilities. The resource allocation in the GPRS network is dynamic and dependent on demand and resource availability. Packets can also be sent in idle periods between speech calls, and the system supports SMS and MMS services. The theoretical maximum throughput in the GPRS system is 160 kbits/sec per MS using all eight channels without error correction coding redundancy (Hakaste et al. 2003).

GPRS facilitates new applications that have not been available in legacy GSM networks due to the speed limitations of circuit-switch data services and the message-length limitation of SMS. GPRS now fully enables users to access Internet applications that they are accustomed to using on their desktop computers, but in mobile environments. For personal applications, GPRS is being used to download mobile ringtones, real-time news and weather reports, stock prices, games, and movie trailers, and to make ticket purchases and restaurant reservations.

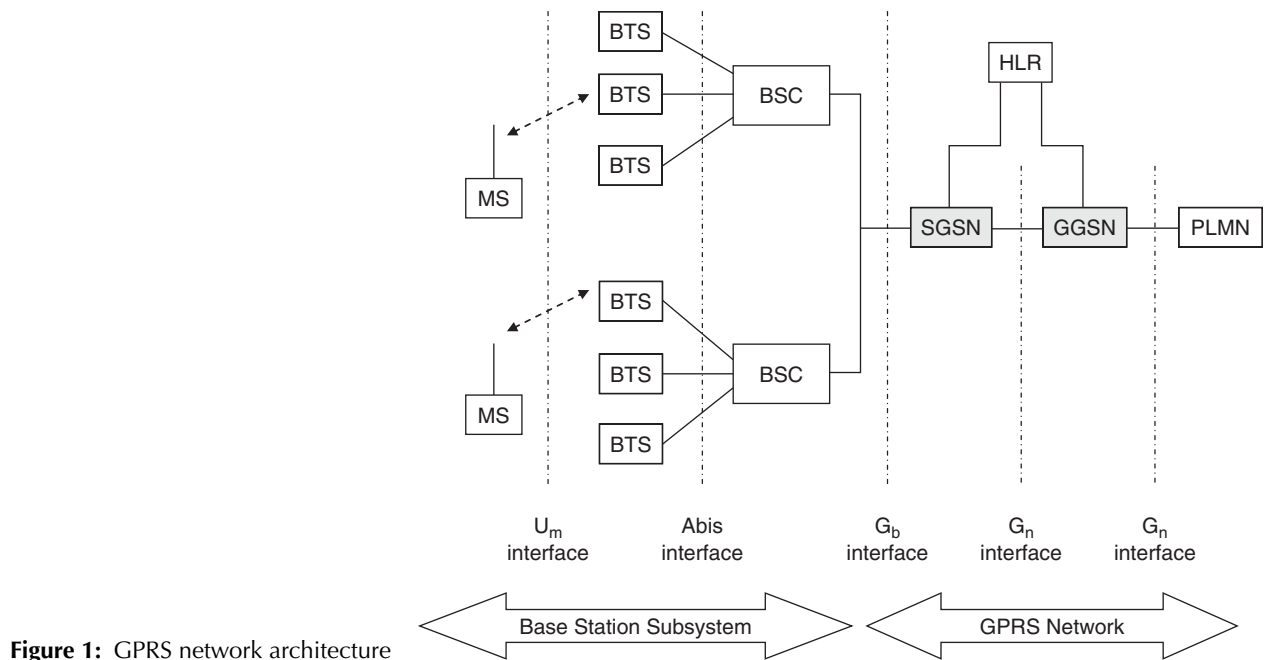

Figure 1: GPRS network architecture

Business applications include Web browsing, e-mail, file transfer, collaborative document preparation, job dispatch, and tech support. Industry observers envision increasing use of wireless data service for transfer of moving images, which can support a host of new applications such as emergency medical service, remote vehicle positioning, stolen-vehicle tracking, and various home automation and security applications. GPRS provides an efficient communication medium for all such applications.

GPRS ARCHITECTURE AND NETWORK ELEMENTS

Some of the GPRS network elements are the same as GSM elements, but GPRS adds certain elements to the underlying GSM architecture. In addition, some software changes must be made in certain GSM network elements in order to support GPRS services. Figure 1 provides a simplified diagram of the GPRS network architecture, with underlying GSM network elements shown unshaded and GPRS-required changes more heavily shaded.

The network elements that are part of the underlying GSM network are as follows:

- MS: mobile station
- BTS: base transceiver station
- BSC: base station controller
- HLR: home location register
- PLMN: public land mobile network

The network elements that must be added or modified in order to enable GPRS service in the GSM network are as follows:

- GPRS-capable mobile station (MS)
- Software upgrade in the BTS

- Software upgrade in the HLR
- SGSN: serving GPRS support node
- GGSN: gateway GPRS support node

The main interfaces for GPRS data transmission, shown in the figure, are:

- Um: air interface or radio interface
- Gb: interface between the BSC and SGSN
- Gn: interface between all SGSNs and also to the GGSN
- Gi: interface between the GGSN and a PLMN

The figure also shows two signaling interfaces toward the GPRS-enhanced HLR from the SGSN and GGSN, respectively.

In the GPRS architecture, the packet-mode traffic is separated from the GSM circuit-mode traffic at the BSC using a packet control unit (PCU), not shown in the figure, which is the principal modification to the BTS for support of GPRS traffic.

As is usually done when describing the legacy GSM system architecture, it is useful to distinguish three broad categories of elements in a GPRS-equipped system: (1) mobile stations, the wireless terminals that customers use; (2) the base station subsystem, which controls the radio links; and (3) the network subsystem, which handles the switching of calls between mobile subscribers and fixed networks, as well as calls between mobile subscribers in the same cellular service network or in different cellular networks. The MSs supporting GPRS service have, of course, considerably increased functionality relative to GSM mobiles, and several classes of GPRS mobile device have been defined, each with different capabilities for supporting data services.

The BSS comprises the base transceiver station, which supports the radio interface, and the base station controller, which controls the assignment of each individual

call connection to an appropriate BTS according to the current location of the mobile subscriber. In any GSM network, each BSC connects to a number of BTSs. In the GPRS upgrade of a GSM network, some software changes must be made to the BTS and the BSC, the changes being concerned mainly with the use of the radio interface for packet-formatted data rather than circuit-oriented data. In addition, some new hardware must be added to the BSC for control of packet data traffic.

Integration of GPRS into the standard GSM architecture also requires the addition of two new network elements shown in the figure: *support nodes*, called the *serving GPRS support node* and the *gateway GPRS support node* (GGSN). An SGSN is connected to the BSS and transfers data packets to and from the MSs within its service area. It performs packet routing and transfer, attachment and detachment of MSs, authentication functions, and logical link management. Associated with each SGSN is a location register, the SLR, not shown in the figure, which stores location information and user profiles for all users registered with that SGSN. The SGSN in turn connects to the GGSN, which provides an interface between an external packet data network, such as the Internet, and the GSM network supporting GPRS service. The GGSN stores information needed to route incoming data packets to the SGSN that is serving a particular mobile. In general, a GGSN can be the interface to an external packet network for several SGSNs, and an SGSN may route its packets to different GGSNs (Eberspächer, Vogel, and Bettstetter 2001; Steele et al. 2001; Bates 2002).

In any communications service network, essential ancillary functions include charging and billing, and the packet nature of GPRS service has a significant influence on the way these functions are implemented. Thus, the GPRS specification provides for a charging gateway function (CGF), which controls the collection of charging data records from the SGSNs and GGSNs. The GPRS specification stipulates the minimum amount of charging information that must be collected, but network operators have considerable latitude in how they implement the CGF function in their networks. Detailed discussion of GPRS billing systems can be found in Bates (2002) and Hoffman (2003).

The following sections describe the main characteristics of the GPRS network elements, with emphasis on their differences relative to the underlying GSM network elements. Detailed information on the GPRS standards can be found in the GPRS specifications, published by the 3GPP standardization group. The specifications can be downloaded from the 3GPP Web site, www.3gpp.org.

GPRS Mobile Stations

In order to have access to GPRS services, the customer must use an entirely new type of mobile station, though these new terminals are backward compatible with traditional GSM voice services. The new MSs are required because existing GSM terminals cannot handle the upgraded radio interface introduced with GPRS. Different GPRS mobiles are designed to provide different levels of service. The GPRS specifications have defined three classes of device, each having its own distinct characteristics.

In order for a device to access GPRS services, it must support at least one of the defined classes. The actual handset implementation will determine whether the class of service is preassigned by the manufacturer, or if the user can change the service class (Bates 2002). The three service classes have been designated as Classes A, B, and C. In discussing these classes of handsets, it is useful to think of the GPRS-overlaid GSM network as a two-branch network (branches splitting at the BSC) capable of serving a single wireless user device. One branch supports circuit-switched connections with the public telephone network, and the other supports connections to packet-switched data networks such as the Internet or business intranets (Lischetzki 2003).

Class A: Class A GPRS devices have the greatest functionality among the three classes. This class of device can connect simultaneously to GPRS and GSM services. The user can access voice and data services at the same time, each service being carried in a single time slot on the radio interface. A Class A device has to support at least two active time slots in both the uplink and downlink directions. The device can access additional time slots to increase the supported data rate.

The Class A device allows the user to transfer data over the packet-switched GPRS branch of the network while simultaneously carrying on a voice call over the circuit-switched GSM branch. Furthermore, the user can initiate and terminate GPRS data sessions and GSM voice calls independently.

The implementation of GPRS Class A services places some significant demands on the network as a whole. In the handsets, clearly, both GSM voice and GPRS data functions must operate in parallel. On the network side, sufficient capacity must be provided to support uninterrupted voice service while also supporting a range of data rates that users will require for a variety of applications. Additionally, in call handoff situations, the receiving cell must be able to provide at least two time slots to handle both voice and data traffic to and from the mobile device.

Class B: A Class B device is able to access both GPRS and GSM services but not simultaneously as in a Class A device. In a Class B device, voice calls and GPRS data sessions are supported sequentially rather than in parallel. When a Class B terminal attaches to the network but has not initiated a GPRS data session, the device operates as a standard GSM voice terminal, initiating and receiving voice calls exactly as it would in a GSM-only network. In this mode, SMS messages can also be transferred. If the user initiates a voice call, GPRS data service is not possible until the voice call has been terminated. During a GPRS data session, the Class B device uses *suspend* and *resume* functions to park data sessions for the duration of voice calls. When a voice call comes in, the user can either continue with the data session, diverting the voice call to voicemail, or suspend (park) the data session for the duration of the voice call. In the latter case, the user may resume the data session after the voice call is completed. A Class B device requires at least one time slot in each direction,

uplink and downlink, which can be used for either voice or data service. Additional time slots can be accessed to increase the data service transfer rate (Lischetzki 2003).

Class C: In contrast with Class A and B devices, a Class C device allows registration on only one service, either voice (with SMS supported) or GPRS data. The GPRS specification has defined three types of Class C devices: Class CC, Class CG, and a combination of the two.

Class CC devices provide only circuit-switched GSM services. These devices function as legacy GSM handsets, supporting voice, SMS, and circuit-switched data services.

Class CG devices support only GPRS services. Legacy GSM circuit-switched voice and data services cannot be supported with these devices.

As a third option, the handset manufacturers can provide devices that allow the user to switch manually between classes CC and CG.

GPRS Multislot Classes

GPRS mobile devices are also categorized by the data rates they can support. Within GSM there are eight time slots on each radio frequency carrier, and each uplink RF carrier is always paired with a corresponding downlink RF carrier. In a legacy GSM network, a circuit-switch service utilizes only one slot in each direction, but in GPRS it is possible to use more than one slot, allowing higher data rates to be achieved when the extra slots are available. The different GPRS data rate capabilities of the devices, referred to as *multislot classes*, are dependent upon the number of slots that can be used in either direction.

GPRS specifies a total of twenty-nine multislot classes, and Table 1 shows those that are most commonly implemented. For each class, the table gives the maximum number of downlink and uplink slots the mobile can support, and the right-hand column gives the upper limit on the combined number of downlink and uplink slots. For example, if a Class 12 mobile is assigned four downlink slots, it can be assigned no more than one uplink slot, since the maximum sum for Class 12 is five slots. Note also that since the specified numbers of slots are maximum numbers, a given mobile device might be able to support more than one multislot class. For example, a Class 8 terminal can also support classes 1, 2, and 4. The permitted multislot configuration also depends on the mobile type: Type 1

mobiles cannot transmit and receive simultaneously, whereas Type 2 mobiles can, and thus can support more time slots. Multislot classes 13 to 29, not included in the table, can be supported only by Type 2 mobile terminals. To date, only one Type 2 device has appeared in the market.

More extensive discussions of the GPRS multislot classes can be found in Bates (2002) and Sanders et al. (2003), and the GPRS specifications appear on the 3GPP Web site, www.3Gpp.org.

Location Registers

The home location register, already an element in any GSM network, must be enhanced to support GPRS services. As in a legacy GSM service network, the HLR serves as the principal database for the network, storing the information related to all subscribers connected to the network and keeping track of the location of each mobile in the network, including the corresponding SGSN for a GPRS mobile. In support of GPRS services, the HLR handles GPRS subscription data, including subscribed quality of service (QoS), and also handles data-packet addressing and mobile roaming (Bates 2002; Bilgic et al. 1999; Priggouris, Hadjiefthymiades, and Merakos 2000).

As in a legacy GSM service network, a visitor location register (VLR) associated with each MSC keeps a temporary database of the subscribers who have roamed into the area served by that MSC. Although the VLR holds information similar to that held in the HLR, it holds information for only those mobiles in the areas being served by its MSC, and a mobile moving out of its serving area is dropped from the VLR's database.

Base Station Subsystem

In the GSM architecture, the base station subsystem comprises the base transceiver station, which handles the radio interface with mobile devices, and the base station controller, which manages the connection of each call between the wired network and the BTS handling the particular RF link connection (Mouly and Pautet 1992; Heine 1999; Eberspächer et al. 2001). In the overlay of GPRS services onto a GSM network, some changes are required in both the BTS and the BSC, but there is greater impact on the BSC than on the BTS. For the BTS, some software upgrades are required to accommodate the changes in the radio interface needed to support packet-formatted traffic. However, the BTS requires no hardware modifications

Table 1: Selected GPRS Multislot Classes

Multislot Class	Downlink Slots	Uplink Slots	Maximum Sum
1	1	1	2
2	2	1	3
4	3	1	4
6	3	2	4
8	4	1	5
12	4	4	5

because the GPRS traffic is carried in the same eight-slot time-multiplexed RF channels that support GSM circuit-switched services. The BSC, however, requires both software upgrades and hardware modifications.

In order to implement GPRS services in a GSM network, the BSC requires a new piece of hardware called a *packet control unit*, which directs the packet data traffic to and from the GPRS network. Each BSC requires installation of one or more PCUs along with a software upgrade. The PCU provides a physical and logical data interface at the BSS for packet data traffic (Bates 2002). When either circuit-switched voice or packet data traffic is sent from the mobile device, it is carried over the radio interface to the BTS, and from the BTS to the BSC, just as in a standard GSM call. However, at the output of the BSC, the traffic is separated—the voice traffic going to the MSC as in standard GSM, and packet data traffic going via the PCU over a frame-relay interface to a new network element called the serving GPRS support node.

Serving GPRS Support Node

In a GPRS network, the SGSN serves as a packet version of a combination of the MSC and the VLR. Not surprisingly, the SGSN employs packet switching, in effect functioning as a router, passing data packets in both directions between the mobile terminal and a public packet data network (e.g., the Internet). In addition to its packet-switching function, the SGSN also handles some of the functions that the BSS handles in a legacy GSM network and is effectively the end point of communication with the mobile device in its GPRS data mode. The SGSN performs the following primary functions:

- Mobility management, including session management, state control, and data packet routing and location tracking on the downlink (toward the mobile)
- Authentication and encryption
- Compression, including TCP/IP header compression and data compression (using V.42 *bis*)

Mobility management is a particularly critical function because customers will expect data sessions to be kept intact as they move about the GPRS service area. The same handoff capability afforded in circuit-switched voice service must be supported reliably in packet data service. This is accomplished in GPRS by defining *routing areas*, which are tracked by the SGSN. Each routing area comprises a number of cells, each cell defined by the signal coverage area of a BTS. As a mobile station moves about a routing area, the SGSN will locate it to a cell and send data packets to it. When the mobile is in active state, the SGSN can track its location to the cell level and promptly deliver arriving data packets. (See the section entitled “Packet Data Handling.”)

Authentication and encryption are essential functions that must be provided in GPRS to prevent intrusion into the network and to protect the privacy of data transferred over the radio interface. These security functions are discussed in the section entitled “Security Procedures.”

In order to make data transfer over the radio interface as efficient as possible, IP packets are compressed before

being encrypted and transmitted. The compression occurs between the MS and the SGSN and is performed by the sub-network dependent convergence protocol (SNDCP) layer of the protocol stack. The compression involves, for example, minimizing the long strings of consecutive ones and zeros in the packet data stream. The compression and expansion are done in a way that ensures the exact reconstruction of the original bit sequence. The SNDCP protocol is specified in 3GPP TS 04.65 (n.d.).

Gateway GPRS Support Node

Although the SGSN supports GPRS data traffic by routing data packets to and from mobile devices, it does not perform all the functions needed to interface that traffic with external packet data networks. The gateway GPRS support node provides this additional functionality. Because users of GPRS services will typically want to access the Internet, each registered user must be provided an IP address for receipt of IP datagrams. Similarly, data originating in an MS must be appropriately addressed for delivery to the intended destination on the Internet. These address resolution functions are performed in the GGSN (Bates 2002; Watts and Wright 2003).

In common networking terminology, a *gateway* is a node that interfaces two networks using different protocols, and this is exactly what the GGSN does in the GPRS architecture. On its GPRS side, the GGSN connects to the SGSN, and on its other side it connects to external packet networks such as the Internet, corporate intranets, and X.25 networks. As seen from the external networks' perspective, the GGSN is simply a router to some subnetwork, because the GGSN conceals the GPRS network infrastructure from the external networks. When the GGSN receives data addressed to a particular GPRS user, it forwards the data to the SGSN currently serving the user's mobile. Data packets originated by the mobile are routed by the GGSN to the appropriate data network. One can see from this discussion that the GGSN performs a function similar to that of the gateway MSC (GMSC) in the GSM architecture. In addition, with respect to handling of IP traffic, its function is much like that of a router.

The GGSN has a mobile-tracking function corresponding to that in the SGSN. If a mobile's location changes beyond the routing area, it can reconnect to a local SGSN, and the GGSN will find it, though data stored in the old SGSN buffers may be lost and have to be retransmitted (e.g., by the transport-layer protocol [TLP]). Data traffic originating in a public packet data network, intended for a GPRS data user, must be directed to a single point of contact; that point of contact is the GGSN. For this reason, the GGSN performs what is sometimes described as the *anchor function* in the GPRS system.

As we have just seen, packet data handling within a GPRS network involves moving packets among SGSNs by way of a GGSN. The delivery of data packets between external data networks and GPRS mobiles is based on the packet handling procedures known as *mobile IP* (Perkins 1998; Mobile IP n.d.). The interconnected subnetwork of support nodes is called the *GPRS backbone*. Within this backbone, the packet data traffic is transported and protected using a protocol called the *GPRS tunneling protocol*

(GTP). In data networking terminology, a tunneling protocol encapsulates one data protocol within another to provide delivery of the encapsulated protocol data units over a network that could not otherwise support that protocol (Leon-Garcia and Widjaja 2000; Tanenbaum 2003). Within the GPRS backbone, the GTP is used to encapsulate IP and X.25 packets, making the underlying transport network invisible to the user data. The GGSN handles the encapsulated packets as follows:

- In the upstream direction, from the mobile to the external packet network, the GGSN removes the GTP and lower-layer headers, and then delivers the IP or X.25 packet in its native form to the external network.
- In the downstream direction, the GGSN performs the opposite operation, adding GTP and lower-layer headers, and transporting the packet to the appropriate SGSN.

PACKET DATA HANDLING

The central purpose of a GPRS network is to transfer packet data between a GPRS mobile terminal and external packet data networks, such as the Internet. There are two essential aspects of the required procedures: *data-packet routing* and *mobility management* (MM). The packet-routing function in GPRS is fundamentally the same as must be performed in any packet-data network. A data packet arrives as a network node, and a routing function in the node determines the node to which the packet should next be sent in order to eventually reach the intended destination. The packet is forwarded to the next node, where the process is repeated. However, in GPRS the packet routing function is complicated by the fact that data packets may be carried across several different networks in order to reach their intended destination (Sanders et al. 2003). The problem here is that the different networks might not use the same form of packet addressing.

The second aspect of GPRS data handling is mobility management. Although MM has been an essential part of all mobile networks, there are some MM features in GPRS that differ from those in circuit-switched network services such as legacy GSM. Since data packets are routed across the network individually, and the MS may be located in different cell areas as individual packets are being routed, the GPRS MM procedure is designed to make optimum use of transmission resources, such as unassigned time slots, in the underlying GSM network.

Before data packets can be transferred between an MS and an external data network, three key steps must be performed:

- The MS must attach itself to the GPRS network. This is phrased purposefully, since the procedure for accomplishing this, called *GPRS attach*, is always initiated by the MS. This is a logical interaction between the MS and the SGSN, taking note of the current location of the MS. Storing and updating the MS location is particularly important for downlink (SGSN to MS) data transfer since this information enables the GPRS network to locate the MS.

- In the next step, called *activation of a PDP context*, a connection is set up between the MS and the GGSN, providing a path for IP packets to traverse inside the GPRS network. When this step has been accomplished, each node in the GPRS network knows how to forward IP packets to the intended MS.
- Finally, the path between the MS and the external data network is set up, enabling transfer of IP packets through the GPRS network to the intended destination.

These procedures are discussed in further detail in the following paragraphs.

GPRS Attach

GPRS attach is a GPRS MM procedure initiated by the MS. Depending upon the settings in the MS, the attach procedure may be performed each time the MS is powered on, or it may be initiated manually by the mobile user. The request for a GPRS attach is made by the MS to the current SGSN by a procedure that is transparent to the BTS and BSC currently serving the MS. First the MS identifies itself and sends its old *routing area identity* (RAI) and desired attach type. The latter indicates to the SGSN whether it wants to attach as a GPRS device, a GSM device, or both. The SGSN then attaches the MS and informs the HLR if there has been a change in the routing area. If the desired attach type is both GPRS and GSM, the SGSN will also update the MS location with the VLR. Once the MS is attached to the SGSN, it remains attached until instructed to detach, thus accounting for the phrase “always on” often used in characterizing GPRS capability.

The result of the GPRS attach procedure is that the current SGSN knows that the MS has activated GPRS. If the MS was already registered with another SGSN, the new SGSN updates the HLR so that the HLR knows the identity of the current SGSN. The HLR then sends the GPRS-specific data for the MS to the current SGSN. The GPRS-specific data corresponds to the different packet data protocol (PDP) contexts that are set up for this specific MS (see next subsection). A PDP context describes the GPRS data connection for an MS. The information describing such a context consists of:

- The *access point name* (APN), a logical name for the desired outside data network. The APN might be a specific Internet address or the address of an Internet service provider.
- The quality of service—including priorities, delays, reliability, and throughput—for the intended application (voice, Web browsing, video, music downloads, etc.).
- The PDP protocol to be used between the MS and the external data network, usually IP.
- The permanent address of the MS, if it has a permanent address.

Several PDP contexts can be set up for an MS such that the MS can reach several IP networks (i.e., several APNs) with different QoS specifications. With respect to QoS, it is worth noting here that some implementations have diverged to varying degrees from the GPRS specifications.

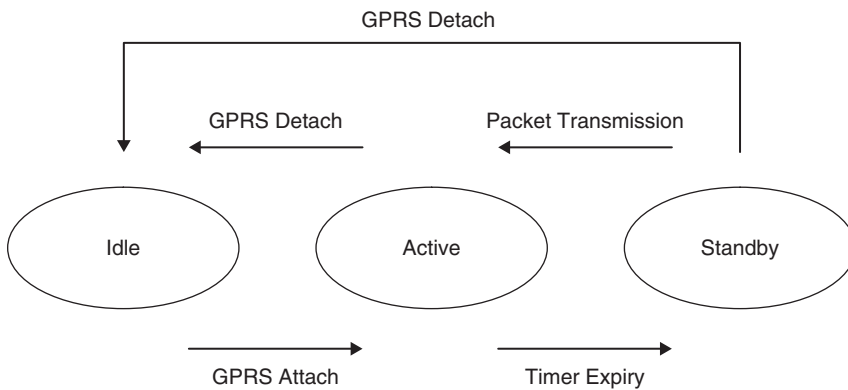

Figure 2: Mobility management states

The messages passed between the MS and the SGSN concerning the GPRS attach procedure are part of the *GPRS mobility management* (GMM) protocol. Other examples of GMM procedures include the updating of MS location (routing area), switching off the MS (GPRS detach), authentication, and GPRS paging.

The final step in enabling the MS to transmit and receive data is activation of a communication session using a packet data protocol context, described next.

PDP Context Activation

A mobile user wanting to start a GPRS service session must activate a *PDP context*, which is in effect a data destination address. A PDP context is used for routing data packets through the GPRS network, between the MS and a GGSN, allowing the MS to exchange data with an external packet data network. The activation procedure begins with the MS sending an activation request to the SGSN. The SGSN then selects a GGSN based on information (APN, QoS, PDP protocol) provided by the MS, and requests the GGSN to provide a context for the MS. Next, the GGSN replies to the SGSN with a tunnel ID (TID), and maps the TID and the SGSN IP addresses to the particular MS associated with them. Finally, the SGSN informs the MS that a PDP context has been activated, and it also updates its information tables with the TID and GGSN IP address with which it has established the protocol tunnel for the MS. (See the section entitled "Gateway GPRS Support Node" for discussion of protocol tunneling in GPRS.) At this point, the entire GPRS network is able to route data packets in either direction between the MS and an external data network.

The preceding paragraph outlined the procedure for mobile-initiated PDP context activation. However, if data arrives at a GGSN for a GPRS mobile user, a PDP context activation can be initiated by that GGSN (Bates 2002).

Once a PDP context is activated, transmission resources are assigned to the communication session until data transfer ceases for a specified interval of time.

Data Packet Transfer

Once the PDP context to an APN selected by the MS has been activated, a logical path is in place between the MS and an external IP network, and packet data transfer can

begin. The GGSN has updated routing information supplied by the SGSN about the current location of the MS, and, as packets arrive from the external network, they are encapsulated using the GTP protocol (see the section entitled "Gateway GPRS Support Node") for transfer over the GPRS backbone to the SGSN currently serving the MS. The GGSN also undoes the encapsulation of MS-originated packets and forwards them to the appropriate external data network.

GPRS Mobility Management

Mobility management is an essential aspect of all mobile communications networks, allowing mobile users to maintain reliable communications sessions while moving about a service network or even roaming from one service network to another. In the case of a GPRS network, the underlying GSM circuit-switched network already has MM protocols in place, but GPRS adds certain MM features that are appropriate for packet-switched traffic while minimizing the required signaling traffic across the network.

Figure 2 depicts the three different states of a GPRS MS: idle, standby, and active. A GSM mobile has two states, idle and active, whereas GPRS adds the standby state to address the packet nature of GPRS traffic.

In the *idle state*, the MS does not have a GPRS context activated or any outside packet network addresses allocated. In this state, the MS is effectively unknown to the GPRS network, and it cannot receive any messages from external data networks; it can only receive those multicast messages that can be received by any GPRS mobile. In the idle state, if the GPRS MS is also a GSM mobile, rather than a GPRS-dedicated mobile, it will be known to the VLR and will make location updates while switched on. However, the GPRS network will not hold any location information for the MS.

In the *standby state*, the MS and the SGSN have established an MM context so that the SGSN location register knows the current routing area of the MS, which can comprise one or more cells within a GSM location area. The MS performs routing area updates as it moves across routing area borders. When the SGSN has to send a packet to an MS that is in standby state, the mobile must first be paged. Because the SGSN knows the routing area in which the MS is currently located, a packet-paging

message is sent to that routing area. Upon receiving the paging message, the MS provides its cell location to the SGSN, and the active state is then established. The use of packet-paging messages simplifies the process of receiving downlink packets. The MS has to listen to only the packet-paging messages, rather than all the data packets being carried in the downlink channels, thus conserving battery power in the mobile.

Once the MS has been paged and responds, it switches to the *active state*, sometimes termed the *ready state*. Additionally, in the SGSN, the MM context is switched to the active state, and packet delivery to the MS begins. In the active state, the SGSN knows the exact location of the MS. Because of the discontinuous nature of GPRS data traffic, the cell selection and reselection are usually performed by the MS; that is, the MS monitors the surrounding cells and decides for itself which one to use. Requests from the MS to use a particular cell may be accepted, or the SGSN may instruct the MS to use a different cell.

When an MS has data packets to be transmitted, access to an uplink channel is needed. The uplink channel is shared by a number of MSs, and its use is allocated by the BSS (BSC and BTS) currently serving the mobile. The MS requests use of the channel with a packet random-access message, using the slotted-Aloha protocol. The BSS allocates an available channel to the MS and sends a packet-access grant message to the mobile. The packet-access grant message includes a description (i.e., one or more time slots) of the allocated channel.

Transition from the active state to the standby state usually occurs upon expiration of the ready timer in the SGSN. This occurs if the MS has not sent or received any data within a period of time set in the timer.

When the subscriber wishes to terminate the GPRS connection, the *GPRS detach* procedure is used. The detach procedure includes transitions either from active to idle or from standby to idle. Such a transition is usually initiated by a detach request from the MS. Upon detachment, the SGSN places the MS in idle state, indicating that the MS is disconnected from GPRS.

More detailed descriptions of GPRS data-handling procedures and MM functions can be found in Halonen et al. (2003), Sanders et al. (2003), Bates (2002), and the GPRS specifications.

Security Procedures

As is the case with any wireless communications service, the radio transmission medium is vulnerable to interception techniques. Thus, to prevent unauthorized intervention in the GPRS system, two primary techniques are employed: authentication and encryption (also termed ciphering). These security procedures are fundamentally the same as those performed in legacy GSM networks, though there are some differences in implementation.

The security procedures utilize information stored both in the mobile terminal's SIM card and in the authentication center (AC). This information includes: (1) an identification key, K_i , which serves as the subscriber's password; (2) an encryption key, K_c , which is calculated anew for each connection; and (3) two algorithms for calculating, respectively, an *authentication key* and an *encryption key*.

Before any GPRS mobile terminal is allowed to have access to the network, it must be authenticated. This procedure insures that the user attempting to initiate a network connection has an authentic SIM card with a valid identification key, K_i . The AC is responsible for generating a set of variables called a *triplet*. A triplet consists of: (1) a *random number*, RAND; (2), a *signed response*, SRES; and (3) an *encryption key*, K_c . The first two variables are used in a challenge-response interchange, initiated and controlled by the SGSN, to authenticate the mobile's SIM card and its identification key K_i . The authentication algorithm is designed to make it extremely difficult for an intruder to calculate the subscriber's identification key K_i (128 bits long), even if he intercepts the RAND and SRES variables on the radio interface.

Once the MS has been authenticated, the calculated encryption key K_c is used to encrypt all the data transferred between the MS and the SGSN. Further details of the GPRS security procedures can be found in Sanders et al. (2003).

GPRS RADIO INTERFACE

The transmission formatting for GPRS is based upon much the same underlying structure as found in GSM; however, there are important differences between the two (ETSI 1997b). As in the GSM specification, each radio channel carries TDMA frames of duration 4.615 ms, each frame containing eight time slots. Also, as in GSM, physical channels are each defined by a combination of frequency channel and time slot for the uplink and downlink, and logical channels are mapped onto physical channels for carrying data traffic and for carrying signaling and control information. However, a number of new logical channels were defined for the GPRS standard. Additionally, many changes in channel structure were made relative to the channel structure defined for GSM circuit-switched services. These changes include a longer multiframe length (described below), new channel-coding schemes, new power-control algorithms, and a link adaptation scheme designed to change the channel-coding scheme according to conditions on the radio channel. The following paragraphs describe how physical and logical channels are assigned to an MS, followed by a brief description of channel coding for GPRS traffic and control channels.

Radio Resource Management

As noted earlier, in a legacy GSM network, a physical channel—which is a time slot in sequentially transmitted TDMA frames—is assigned to an MS throughout the call session, whether information is being transmitted or not. Furthermore, a time slot is assigned in both the uplink and the downlink. In contrast, GPRS assigns time slots in a more flexible manner that is better suited to the transmission of discontinuous data packets. A GPRS MS can transmit on multiple time slots in the same TDMA frame; this is termed *multislot operation*. The number of time slots assigned to an MS corresponds to the multislot class, as discussed in the section entitled “GPRS Multislot Classes.” In a further contrast with legacy GSM, the

numbers of uplink and downlink time slots are assigned separately, which enables efficient use of radio resources in cases of asymmetric traffic, such as Web-browsing applications.

In a GPRS-equipped GSM network, the radio resources of each cell are to be shared among all MSs, both standard GSM and GPRS, currently located in the cell's signal coverage area. In GPRS, the assignment of physical channels to either circuit-switched GSM service or packet-switched GPRS service can be done dynamically. A physical channel allocated for GPRS data transmission is termed a packet data channel (PDCH), and the number of PDCHs can be adjusted in response to the current traffic demand. Physical channels not currently needed for circuit-switched GSM calls can be assigned as PDCHs, for example, enabling faster delivery of GPRS packet data traffic. Similarly, if there is increased demand for GSM traffic, PDCHs can be deallocated.

The ability of GPRS to dynamically assign multiple time slots to packet data traffic is particularly valuable given the real-world characteristics of wireless data transmission. Under some conditions, received signal quality can be degraded; GPRS deals with this in the *radio link control* (RLC) layer of the protocol stack using error-detection and *automatic repeat request* retransmission of erroneous data. Under very poor signal conditions, large numbers of retransmissions can significantly slow the delivery of data across the radio interface, and the ability to dynamically assign multiple time slots for data delivery can help to offset the effects of high retransmission rate. More detailed discussion of the RLC layer can be found in Eberspächer et al. (2001).

When a particular MS has finished transmitting or receiving its data packets, its assigned PDCHs are released. In this way, multiple MSs can share a physical channel, enabling the efficient use of the radio resources.

Management of Logical Channels

Here we briefly describe the process of allocating transmission resources to an MS for transfer of GPRS data. As in legacy GSM, logical channels in GPRS are divided into two categories, traffic channels and control channels. The *packet data traffic channel* (PDTCH) is used for the transfer of user data. The control channels comprise three categories: the *packet broadcast channel* (PBCCH), four *packet common control channels* (PCCCHs), and two *packet dedicated control channels* (PDCCHs). To provide a simple example of channel allocation, assume that an MS has data packets to transfer to some destination through the GPRS service network. The MS requests a traffic channel by sending a packet channel request on the *packet random access channel* (PRACH), which is one of the four PCCCHs. Alternatively, the request may be sent on the *random access channel* (RACH) of the underlying GSM network. The BSS responds on the *packet access grant channel* (PAGCH), which is another of the four PCCCHs. If the MS made its channel request on the GSM RACH, the BSS responds on the *GSM access grant channel* (AGCH).

Once the MS's channel request is granted, a *temporary block flow* (TBF) is established between the MS and the BSS. The TBF is a physical connection for transfer of

packet data units (PDUs) in one direction over the radio interface. If bidirectional data transfer is needed, two TBFs are established, one uplink and one downlink. When data packets arrive from the network intended for a particular MS, the BSS pages the MS with a *packet paging request*, and the MS initiates the channel allocation with a packet channel request, as in the MS-initiating example.

There is at most one TBF established per MS per direction, but each TBF can be mapped onto multiple PDCHs. TBFs established for different MSs can share the same PDCH or a group of common PDCHs. As its name implies, TBF is a temporary connection maintained only for the duration of data transfer; when all of the PDUs have been transferred, the PDCHs are released, making them available for other data transfers.

It is important to point out that data transfer over the GPRS radio interface will have characteristics much different from the familiar situation of data communication using modems on the public telephone network. Wireless communication sessions will invariably exhibit intervals of poor signal quality with the potential of imposing errors on the transferred data. GPRS accommodates these situations by providing for the optional use of acknowledge (ACK) mode operation, with retransmission, in the *radio link control* (RLC) layer of the system. The retransmission of erroneous RLC blocks under degraded signal conditions has a direct effect upon *data throughput*, that is, the amount of data delivered successfully to the user per unit of time. Correspondingly, there is a direct impact on the delay characteristics of the delivered data packets. In addition, the throughput and delay characteristics of GPRS data transfer will be affected by the traffic load on the network, along with the availability of traffic channels as each channel request is made. Detailed treatments of TBF throughput and delay characteristics can be found in Halonen et al. (2003) and other references cited therein.

It is beyond the scope of this chapter to describe all of the details of the GPRS radio interface and the management of its radio resources, but the reader may find these details in a number of recent texts (see Halonen et al. 2003; Seurre, Savelli, and Pietri 2003; Steele et al. 2001). The following subsection describes the multiframe structure of a GPRS physical channel.

Multiframe Structure

Figure 3 shows the structure of a 240-ms GPRS multiframe, which contains fifty-two TDMA frames, each with eight time slots. A GPRS multiframe has the same duration as two GSM multiframes, each containing twenty-six TDMA frames. The GPRS multiframe contains twelve blocks (B0–B11) of four consecutive TDMA frames plus four idle frames. A physical channel is referred to as a packet data channel, fully defined by a frequency channel together with one uplink time slot and one downlink time slot. On any given PDCH, blocks of four bursts, called radio blocks, form the logical channels, carrying either user data or signaling information. Each radio block consists of 456 bits. The packet data logical channels are mapped dynamically onto the radio blocks B0–B11 of the multiframe. The mapping can change from one radio block to another, controlled by parameters broadcast on a packet

Figure 3: GPRS multiframe structure

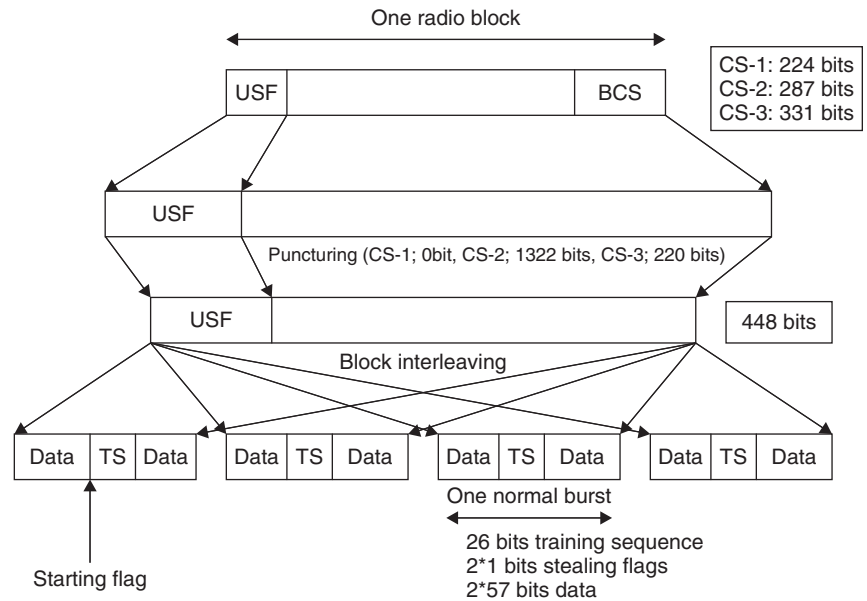

Figure 4: Radio block encoding for three GPRS coding schemes (CSs)

broadcast control channel. This dynamic mapping function allows the system to adapt to the traffic load by allocating or releasing resources as needed (Seurre et al. 2003).

An important feature of the GPRS specification is the provision of four *coding systems* (CSs) providing different degrees of error protection. The lowest coding rate (greatest redundancy) is provided by CS-1 and the highest rate (no redundancy) by CS-4. The coding uses a cyclic redundancy check (CRC) code together with convolutional channel coding for CS-1, CS-2, and CS-3. For CS-4, only CRC coding is used, providing error detection without error correction. Code puncturing (selective removal of parity bits) is applied to the convolutional encoding output to adjust the transmitted bit sequence to the radio block length. To illustrate the channel-coding scheme, Figure 4 shows the encoding of one radio block for coding systems CS-1 to CS-3.

The GPRS specification includes a link adaptation procedure for choosing the coding system in accordance with the measured radio transmission environment. However, link adaptation has generally not been implemented in deployed equipment, and, as a practical matter, CS-1 is typically used for signaling and CS-2 for packet data transfer.

ENHANCED DATA FOR GLOBAL EVOLUTION

Soon after the introduction of GPRS in 2000, network operators perceived that GSM-based networks would have to

provide even higher data rates. The need for higher rates has grown out of the market demand for an expanding menu of services, such as multimedia transmission. In response to this market demand, the European Telecommunications Standards Institute (ETSI) defined a new family of data services, built upon the existing structure of GPRS. This new family of data services was initially named enhanced data Rates for GSM evolution and was subsequently renamed *enhanced data for global evolution* (EDGE). Although the primary motivation for the EDGE development was enhancement of data services in GSM/GPRS networks, EDGE can also be introduced into networks built to the IS-136 (U.S. digital cellular) standard (Furuskar et al. 1999). In Europe, EDGE is considered a 2.5-generation (2.5G) standard, providing a transition between 2G and 3G systems. As is the case with GPRS, a GSM network operator requires no new license to implement EDGE services in its network, since the 200 kHz RF channel organization of conventional GSM is reused with a different organization of logical channels within each RF channel. This section describes the implementation of EDGE in GSM/GPRS networks.

EDGE enhances data service performance over GPRS in two ways. First, it replaces the GMSK radio link modulation used in GSM with an eight-PSK modulation scheme capable of tripling the data rate on a single radio channel. Second, EDGE provides more reliable transmission of data using link adaptation, which dynamically chooses a *modulation and coding scheme* (MCS) in accordance with the current transmission conditions on the radio channel. The EDGE link adaptation mechanism is

Table 2: EGPRS Modulation and Coding Parameters

Modulation and Coding Scheme	Code Rate	Modulation Type	Data Rate per Time Slot (kb/s)	MCS Family
MCS-9	1.00	8-PSK	59.2	A
MCS-8	0.92	8-PSK	54.4	A
MCS-7	0.76	8-PSK	44.8	B
MCS-6	0.49	8-PSK	29.6	A
MCS-5	0.37	8-PSK	22.4	B
MCS-4	1.00	GMSK	17.6	C
MCS-3	0.80	GMSK	14.8	A
MCS-2	0.66	GMSK	11.2	B
MCS-1	0.53	GMSK	8.8	C

an enhanced version of the link adaptation mechanism introduced and specified in GPRS (Halonen et al. 2003; Seurre et al. 2003). EDGE also improves upon GPRS by incorporating a new hybrid ARQ technique called *incremental redundancy* (IR). In the IR scheme, when an RLC data block is received with detected errors and must be retransmitted, reception of each retransmission of that block combines information from previous transmissions in order to increase the probability of an eventual error-free reception of the block.

EDGE provides two forms of enhanced data service for GSM networks: *enhanced circuit-switched data* (ECSD) for circuit-switched services and *enhanced GPRS* (EGPRS) for packet-switched services. In each form of EDGE data service, there are provisions for combining logical channels (time slots) in the GSM transmission format to provide a wide menu of achievable data rates.

The major impact that EDGE has on the GSM/GPRS protocol structure is at the physical layer of the radio interface, and there is only minor impact on medium-access control (MAC) and radio link control (RLC) layers (Halonen et al. 2003). The EDGE RF specification and definition of burst structures are common to EGPRS and ECSD. A major modification in EGPRS, relative to GPRS, is the *link quality control* (LQC) function, which provides a wider array of link error-control schemes than exist in conventional GSM or in GPRS. The LQC function provides nine different modulation and coding schemes, MCS-1 to MCS-9, as well as related signaling and adaptation procedures for switching between MCSs in response to radio link conditions. Table 2 summarizes the nine MCSs used in EGPRS and shows the data throughput provided by each MCS. The EGPRS modulation and coding schemes are organized into three families, A to C, according to their RLC block sizes. For example, in Family A, MCS-9 carries 1,184 payload bits in two RLC data blocks during one EGPRS radio block of four consecutive bursts (radio blocks). MCS-6 carries 592 payload bits in one RLC frame, and MCS-3 carries 296 payload bits within the RLC block. In each family, the numbers of payload bits carried in the lower-rate coding schemes are submultiples of the payloads at higher rates. This feature

enables efficient retransmission of negatively acknowledged RLC blocks when this functionality is needed following a sudden change in radio channel conditions. For a detailed discussion of EGPRS link adaptation and analysis of its performance, see Halonen et al. (2003).

The ECSD service is built upon the HSCSD service standardized in the GSM Phase 2+ specification. Although the user data rates provided by ECSD (up to 64 kb/s) are not higher than those in HSCSD, the same data rates are achieved in ECSD by using smaller numbers of time slots and simpler implementation in the mobile terminals (Halonen et al. 2003). As was the case with HSCSD, ECSD provides both *transparent* (T) and *non-transparent* (NT) services. Transparent data service employs forward-error correction and is characterized by a fixed time delay in data delivery. Generally speaking, transparent service cannot assure a specified level of accuracy in delivered data. Non-transparent data service uses a *radio link protocol* (RLP) that includes error detection and retransmission, termed *automatic repeat request* (ARQ), to assure that the error rate in delivered data will be maintained below some specified level (Lin and Costello 2004). The use of retransmission results in variable time delay in the delivered data. Table 3 shows the data rates provided by ECSD service in EDGE.

THE EVOLUTION GOES ON

In the last few decades, the telecommunications industry has become very responsive to market demands for new services and capabilities. This has been particularly true of the wireless segment of the industry, which has seen vigorous growth from cordless phones and first-generation analog cellular networks through 2G digital networks, low-speed mobile data networks, paging systems, and now 3G technologies that provide improved voice quality and the integration of voice and data services. Two dominant themes have been discernable throughout this wireless evolution: the growing dependence on mobility, and the increasing importance of data services in the mobile environment (see Pahlavan and Levesque 2005).

Table 3: ECSD Service Data Rates in EDGE

Coding Scheme	Code Rate	Modulation Type	Gross Rate (kb/s)	Radio Interface	User Rate (kb/s)
TCH/28.8 (NT/T)	0.419	8-PSK	69.2	29.0	28.8
TCH/32.0 (T)	0.462	8-PSK	69.2	32.0	32.0
TCH/43.2 (NT)	0.629	8-PSK	69.2	43.5	43.2

NT = non-transparent Service; T = transparent service

The earliest cellular networks were driven by the voice service market, that is, “cutting the telephone cord” and allowing the customer to have untethered access to the public telephone network for standard voice calls. Consequently, the early cellular networks were designed as circuit-switched networks, simply adding user mobility to traditional dialup phone service. With the introduction of digital transmission in the 2G cellular networks, data services were provided, but data calls were circuit switched as were traditional voice calls, and the available data rates were modest. For a number of years, this was considered a satisfactory way of supporting cellular data service, since early demand for mobile data service was limited, and service providers were concerned primarily with meeting the rapidly growing market for cellular voice service. However, the market for mobile data services, slow to emerge, began to take on increasing importance. Today, the terms “mobile office,” “road warrior,” and “M-commerce” are familiar references to the increasing use of wireless data communications as part of everyday business.

A major driver in the growth of demand for mobile data was the tremendous expansion in use of the Internet and the World Wide Web and the growth in popularity of new applications requiring data service. The traveling business or professional person is increasingly dependent upon wireless access to e-mail, FTP file transfers, Web site access, and even video teleconferences. Other applications have also emerged for handling financial transactions, traffic inquiries, fleet management, alarm notification, and many other functions. These emerging applications and markets have produced a growing demand for wireless data services, and, as users gain familiarity with the use of these services, their levels of expectation continually rise. SMS is a prominent example; since its inception, SMS has become extremely popular as a means for rapidly exchanging alphanumeric text messages, and this has led to a demand for wireless exchange of digital images and even multimedia video clips using MMS. Another phenomenon is the increasingly popular use of wireless communications to download music files, games, ringtones, and custom screens from the Web.

As the demand for wireless data services grew, the limitations of the circuit-switched architecture became obvious. Every cellular service network operates within a fixed spectrum allocation, perhaps licensed at a high capital cost, and frequency channels allocated to circuit-switched data service are not available for voice service, creating a capacity problem as demand for both voice and data services grows. Furthermore, since most data

applications are discontinuous in nature, packet-switched data service is well suited to those applications, and the GPRS architecture, by overlaying packet-switching onto legacy GSM networks, provided a nondisruptive solution. However, as wireless data service grows in acceptance and popularity, the demand for ever-higher data rates continues. The EDGE service, summarized in the previous section, addresses the data rate requirement by changing the physical-layer modulation scheme, allowing more data to be transmitted in each time slot of the underlying GSM transmission format.

The next stage of the GSM evolution is the 3G standardization initiative, intended to combine and gradually replace 2G digital cellular voice and data services. The 3G systems are expected to improve voice quality, expand network capacity, and increase the data rates of wireless data services. The primary set of requirements for 3G systems is referred to as *International Mobile Telecommunications Beyond the Year 2000* (IMT-2000). Although the 3G initiative was originally envisioned to result in a single, unified, worldwide standard, in reality several approaches have been pursued. The two leading approaches are as follows.

- Universal mobile telephone system, which is based on W-CDMA technology, will also incorporate GPRS and EDGE services in areas in which the highest data rates provided by W-CDMA are not needed. Thus, the UMTS approach is attractive to service providers that already have major capital investments in GSM-based networks. With respect to its high-speed data services, UMTS provides rates up to 144 kbits/s for vehicular users, up to 384 kbits/s for pedestrian users, and up to 2 Mbits/s for indoor users. However, the achievable performance will in reality depend upon a number of factors, including network engineering and the traffic loads experienced in the service networks.
- The CDMA-2000 system, which builds upon the earlier CDMA systems, IS-95 and cdmaOne (Viterbi 1995; Steele et al. 2001). CDMA-2000 supports data rates ranging from 144 kbits/s to over 3 Mbits/s.

Looking beyond 3G, several developments are under way, including *high-speed downlink packet access* (HSDPA), a variation of 3G also called 3.5G. HSDPA utilizes versions of link adaptation and IR, techniques already employed in EDGE. It is seen by some industry observers as a strong candidate to succeed 3G in GSM-based networks. In December 2005, Cingular announced availability of HSDPA

in sixteen U.S. cities, with average data speeds of 400–700 kbps, under the brand name “BroadbandConnect.”

High-speed uplink packet access (HSUPA) is a data access protocol similar to HSDPA, also utilizing link adaptation and IR, with upload speeds up to 5.8 Mbit/s (Holma and Toskala 2006). HSUPA is being referred to as 3.75G or sometimes 4G technology. The specifications for HSUPA are still under development and will be included in UMTS Release 6.

At this writing, the vision for enhancements of 3G networks and for evolution of 4G wireless networks is still being formulated. Indeed, the term 4G is being used with somewhat different meanings; an alternative term, perhaps more appropriate, is “beyond 3G”—a broader designation encompassing a number of different but overlapping technologies.

Although the designation for the wireless generation beyond 3G is not settled, the technical objectives are being formulated. The data service rates for 4G are planned to be up to 20 Mbps for high vehicular speeds and 100 Mbps under stationary conditions. Network capacity will be at least ten times greater than in 3G networks, and seamless connectivity and global roaming will be provided across multiple networks. Some observers foresee an all-IP architecture for 4G, based entirely on packet-switched networking, eventually enhanced by the promulgation of the IPv6 network-layer standard.

An important 4G application is projected to be high-quality streamed video. Some observers believe, however, that transferring music files will be a “killer application,” a belief based on the enormous market success of the iPod. At present, using 3G services, only very short music clips can be downloaded. 4G is likely to enable the download of full-length songs or music selections, which may change the market response dramatically.

Though the overall market for cellular services continues to be dominated by voice service, the demand for cellular data services grows steadily and is paralleled by the growth in use of wireless data transport in other technical regimes, such as wireless fidelity (WiFi) and Worldwide Interoperability for Microwave Access (WiMax). Many people in the telecommunications industry have long observed that customers pay for services, not technology, and this has been particularly true in the case of wireless data, where customer use of the technology has been shaped not by the technical capabilities of the service networks but rather by the steady evolution of new uses and applications.

Today we see such uses as music and video downloading, multiplayer gaming, and location-based services, applications that were not even envisioned when early wireless data systems were being conceived and standardized. It is safe to assume that as the wireless data industry continues to evolve, there will be customer demand for constantly higher data rates, and the industry will respond with new approaches to meeting these demands while also finding ways to increase efficiency in use of spectrum, which in the final analysis is always limited. Along with demands for steadily higher data rates, many industry observers also foresee a pattern of convergence, not only in integrated use of voice and data services but in intermingled use of data drawn from diverse sources. As always, customers will shape the market, and the technology will follow.

CONCLUSION

This chapter describes the basic concepts of GPRS, the mobile services it provides, and its relationship to the underlying GSM network architecture. The development of the GPRS system has enabled GSM network operators to leverage their considerable infrastructure investments by adding packet-switched data services to legacy networks designed originally for strictly circuit-switched digital voice and data services. The packet nature of GPRS is much better suited than is circuit-switched service to mobile data applications that generate inherently bursty traffic, enabling GPRS-equipped networks to achieve considerable efficiency improvements in the use of valuable spectrum radio spectrum. Another significant benefit yielded by GPRS, EDGE, and the evolving new generations of mobile data services is the enhancement of capabilities for digital communications across diverse networks. This becomes increasingly important as we see the steady progress toward convergence of network technologies, particularly wireless networks and the Internet, and the growing popularity of mobile Internet service, mobile TV, and mobile multimedia services.

GLOSSARY

- 1G:** First-generation mobile wireless technology, employing analog signal modulation. Prominent examples included AMPS, deployed in North America, and TACS, deployed in many parts of Europe.
- 2G:** Second-generation mobile wireless technology, employing digital voice coding, digital modulation, and providing both voice and data services.
- 3GPP:** 3rd-Generation Partnership Project, an international cooperative agreement established in 1998 to produce a global 3G mobile phone system specification. 3GPP is a project under the aegis of the European Telecommunications Standards Institute (ETSI).
- BSC:** Base station controller, a GSM network element that controls traffic between an MSC and one or more BTSs. A BSC controls the handover of call connections from one BTS to another as a mobile user moves around a service network.
- BSS:** Base station subsystem, an entity defined in the GSM architecture, comprising the BSC and the BTS.
- BTS:** Base transceiver station, the GSM network element that supports radio coverage for mobile users within a limited geographical area. A BTS will typically include a number of radio transceivers, power amplifiers, and antennas, as well as signal processing elements.
- CS-1, -2, -3, -4:** Coding systems that provide different levels of error protection in GPRS data services.
- EDGE:** Enhanced data for global evolution, a service that builds upon the GPRS architecture and other improved data services envisioned for the Universal Mobile Telecommunication System (UMTS).
- EGPRS:** Enhanced GPRS, a service that allows combining time slots in the GSM transmission format to provide a wide menu of achievable data rates.
- HSCSD:** High-speed circuit-switched data, a service that allows a mobile station to access up to four time slots in each TDMA frame on a GSM channel.

- IP:** Internet protocol, the network-layer protocol implemented throughout the Internet.
- MS:** Mobile station, the wireless terminal used by a cellular service customer.
- MSC:** Mobile switching center, the GSM network element that provides the interface between wired public networks and the wireless network.
- PCU:** Packet control unit, a hardware element added to a BSC to handle GPRS data traffic.
- PDCH:** Packet data channel, a physical transmission channel defined by a frequency channel together with an uplink and a downlink time slot.
- Phase 2+:** A version of the GSM specification incorporating several new data services, including HSCSD and GPRS.
- PSTN:** Public switched telephone network, the legacy wired telephone network, providing traditional analog voice service as well as support for dialup modems and fax machines.
- QoS:** Quality of service, a profile of data-transfer attributes, which may be selected by the user on a per-call basis. The user may have different requirements relating to time delay and data reliability for different data applications.
- SGSN:** Serving GPRS support node, a network element added to a GSM network to route data packets in both directions between a GPRS handset and packet data networks, such as the Internet and X.25 networks.
- SMS:** Short message service, a bidirectional GSM service for transferring short alphanumeric messages, with a store-and-forward capability.
- SNDCP:** Sub-network dependent convergence protocol, a mapping and compression function residing between the network layer and lower layers of the GPRS protocol stack. It also performs segmentation, reassembly, and multiplexing.
- Support nodes:** A term that encompasses the SGSN and GGSN, network elements added to a GSM network in order to support packet data services.
- TDMA:** Time-division multiple access, a transmission scheme in which multiple users share a frequency channel, each user being given access to one or more repetitive time slots in the transmitted bit stream.
- UMTS:** Universal mobile telecommunications system, one of the 3G mobile phone technologies, standardized by 3GPP. It uses wideband CDMA as the underlying standard. To distinguish UMTS from competing network technologies, UMTS is sometimes called 3GSM, emphasizing the combination of the 3G nature of the technology and the GSM standard that it was designed to succeed.

INTRODUCTION

Cellular communication allows subscribers to make and receive calls from anywhere. In the United States, cellular communication was first deployed at the 800MHz band. In order to accommodate more subscribers, the FCC (Federal Communications Commission) allocated the 1900MHz band for PCSs. PCS uses a cellular network as its infrastructure. In a cellular network, a service coverage area is divided into smaller areas called cells, each of which is served by a base station (Black 1996; Rappaport 2002). Mobile terminals (also known as mobile stations) such as cell phones within a cell can be reached wirelessly through the corresponding base station. In order to reach a mobile terminal, the cellular network needs to know the cell in which the mobile terminal is located. Location management deals with how to find the cell location of a mobile terminal that is not in a call.

There are two operations in location management: location update and paging. The cellular network performs the paging operation. The goal of this operation is to find the cell in which the mobile terminal is located when an incoming call arrives for it. Once the mobile terminal is located, the incoming call can be routed to the corresponding base station. The location update operation is performed by the mobile terminal. When performing the location update operation, the mobile station sends to the network its current cell location and other related information depending on the specific location management scheme. The number of cells to be paged in the paging operation usually depends on how frequently the location update operation is performed.

The current cellular network uses the location areas location management scheme (Rahnema 1993). In this scheme, the service coverage area is divided into location areas, each of which consists of contiguous cells. When a mobile terminal enters a new location area, it needs to update its location (i.e., the new location area) with the network. When an incoming call arrives for the mobile terminal, the network pages all the cells within the location area last reported by the mobile terminal. The location areas scheme is global in the sense that all mobile terminals update their locations in the same set of cells, and it is static in

the sense that the location areas in the network are fixed (Bar-Noy, Kessler and Sidi 1995; Ramanathan and Streenstrup 1996). In contrast, a location management scheme is individualized if each individual terminal can decide when and where to update its location, and it is dynamic if a mobile terminal can update its location in any cell instead of in a pre-defined set of cells. In this chapter, individualized and dynamic schemes as well as global and static schemes will be described.

The call arrival rate and the mobility of mobile terminals can greatly affect the design of a location management scheme. If the call arrival time to a mobile terminal is known beforehand, the mobile terminal can update its location just before the call arrives. In this way, the number of location updates and the scale of paging (i.e., the number of cells to be paged) will be minimized. Similarly, if the mobility of a mobile terminal is known or can be predicted, only the cells on the predicted or known mobility path need to be paged. This will also reduce the number of locate updates and the scale of paging. In this chapter, the location management schemes that take advantage of the call arrival rate and the mobility of mobile terminals will be discussed.

In the location areas scheme, no matter how well the location areas are designed, there is a ping-pong location update effect when a mobile terminal moves back and forth between two neighboring location areas. This chapter presents several location management schemes proposed to reduce or eliminate the ping-pong effect, thereby effectively reducing the number of location updates. In the location areas scheme, all the cells in the last-reported location area are paged simultaneously. If a paging delay is allowed, the paging task can be divided into multiple rounds and the most probable set of cells will be paged first. This will greatly reduce the number of cells to be paged to locate the mobile terminal. In this chapter, we will also discuss selective paging schemes that minimize the number of cells to be paged within a constrained paging delay.

This chapter introduces location management in PCS networks. It does not offer an exhaustive description of all location management schemes. Its focus is the location areas scheme currently used in PCS networks.

(For detailed classification of location management methods, the reader is referred to a recent article in Kyamakya and Jobmann 2005.) Specifically, this chapter introduces the location areas scheme, discusses its weak points, and presents some advanced schemes to overcome these weak points. The rest of this chapter is organized as follows: The Current Location Areas Scheme describes the location areas scheme, Global and Static Schemes deals with global and static schemes, while Individualized and Dynamic Schemes discusses individualized and dynamic schemes. Call-Arrival-Rate and Mobility-Based Schemes presents several location management schemes that take advantage of the call arrival rate and the mobility of mobile subscribers. Ping-Pong-Effect Reduction Schemes discusses the location update schemes that can reduce or eliminate the ping-pong effect, and Selective Paging Schemes presents selective paging schemes. Finally, Conclusion provides a summary.

THE CURRENT LOCATION AREAS SCHEME

The location areas scheme is used in current cellular networks. In the location areas scheme, the whole service coverage area is divided into location areas, each of which consists of contiguous cells. The base station of each cell broadcasts the ID of the location area to which the cell belongs, in addition to its cell ID. Listening to the control channels of the base stations, a mobile terminal knows whether it is moving out of (or into) a cell as well as a location area. The base stations in a location area are connected to a mobile switching center (MSC). An MSC is connected to the PSTN (Public Switched Telephone Network) and the PSPDN (Packet Switched Public Data Network) in a personal communication system.

Figure 1 illustrates a typical cellular network for a personal communication system in which each cell is

Figure 1: A typical PCS cellular network

represented by a hexagon, and each base station is represented by a triangle. Each mobile subscriber or terminal is associated with a home MSC. (The terms subscriber and terminal will be used interchangeably hereafter.) A mobile subscriber considers an MSC as the home if the mobile subscriber has subscribed for wireless services from the MSC. Each MSC has two main databases: HLR (Home Location Register) and VLR (Visitor Location Register). HLR contains information about each mobile subscriber that considers the MSC as the home. VLR contains information about the visiting mobile subscribers that are currently located in the location area covered by the MSC.

When an incoming call arrives for a mobile terminal, it is first routed to the home MSC of the mobile terminal. The current location area of the mobile terminal in HLR is checked to determine whether the mobile terminal is located within the home MSC or within another MSC called the visited MSC (to be explained later). If the mobile terminal is located within a visited MSC, the call will be routed to the visited MSC. The visited MSC or the home MSC will be responsible for locating the mobile terminal in the corresponding location area. This process is called paging.

When a mobile terminal moves out of the location area covered by the home MSC, it enters a neighboring location area. The MSC in charge of the location area that the mobile terminal just entered is called the visited MSC, and the mobile terminal needs to register with the visited MSC. The visited MSC will record the fact that the mobile terminal is located within its location area in its VLR and will notify the mobile terminal's home MSC of the current location area. The home MSC will record the mobile terminal's current location area in its HLR. If the mobile terminal enters the visited MSC from another visited MSC, the home MSC also needs to notify the old visited MSC, and the old visited MSC removes the record about the mobile terminal from its VLR. This process is called location update.

Location update and paging are two operations of a location management scheme. The location management cost is the sum of the location update cost and the paging cost. As shown in the previous two paragraphs, in both location update and paging operations, there are a lot of signaling activities over the wireline part and the wireless part of the cellular network. Each signaling activity has a cost. However, only the wireless signaling cost is usually considered. This is mainly because the radio frequency bandwidth is limited and is not readily expandable. In contrast, the bandwidth of the wireline network is easily expandable. Therefore the paging cost is in proportion to the total number of cells paged by the cellular network, and the location update cost is in proportion to the total number of location updates made by mobile terminals.

There is a trade-off between the location update cost and the paging cost. Consider two extreme cases for the location areas scheme, namely the Never-Update and Always-Update cases (Bar-Noy, Kessler, and Sidi 1995). In the Never-Update case, there is only one location area for the whole service area; therefore no location updates are necessary and no location update cost is incurred. In this case, the paging cost will reach the maximum because the cellular network needs to page all the cells to locate a mobile terminal. In the Always-Update case, each cell

forms a location area. In that case, the maximum location update cost will be incurred because a mobile terminal needs to update its location whenever it enters a cell. However, the cellular network knows exactly which cell a mobile terminal is in. When an incoming call arrives for a mobile terminal, the call can be directly routed to the cell last reported by the mobile terminal without paging. Therefore the paging cost is kept to the minimum. In general, if a mobile terminal updates its location more frequently, the location update cost will be higher. However, the cellular network will usually better know the location of the mobile terminal. Therefore the paging cost will be lower when an incoming call arrives for the mobile terminal.

GLOBAL AND STATIC SCHEMES

A location management scheme can be either global or individualized (Bar-Noy, Kessler, and Sidi 1995; Ramanathan and Steenstrup 1996). A location management scheme is global if all the mobile terminals update their locations at the same set of cells, and it is individualized if an individual terminal is allowed to decide when and where to perform its location update. A location management scheme can also be classified as either static or dynamic (Bar-Noy, Kessler, and Sidi 1995; Ramanathan and Steenstrup 1996). A location management scheme is static if a mobile terminal needs to perform location updates at a fixed set of cells, and it is dynamic if a mobile terminal can perform its location update at any cell, mainly because of its mobility. Usually a global scheme is static, and a good individualized scheme is dynamic. The location areas scheme used in the current system is global because all mobile terminals update their locations in the same set of cells, and it is static because the location areas are fixed. The division of location areas is usually determined by the aggregate mobility behavior and call statistics. In principle, a division should be made such that the total location management cost is minimized.

Use of reporting cells, also known as reporting centers, is another popular global and static scheme (Bar-Noy and Kessler 1993; Hae and Zhou 1997). In the reporting cells scheme, a subset of cells is designated as reporting, and the others non-reporting. A mobile terminal needs to update its location when it enters a new reporting cell. When an incoming call arrives for a mobile terminal, the cellular network pages all cells within the vicinity of the reporting cell last reported by the mobile terminal. The vicinity of a reporting cell is defined as the set of all non-reporting cells that are reachable from the reporting cell without crossing another reporting cell. For simplicity's sake, a reporting cell belongs to its own vicinity. Figure 2 illustrates four reporting cells (shown in shade) in a one dimensional cellular network. The vicinity of a reporting cell, say cell 8, consists of cells 4, 5, 6, 7, 9, 10, and 8 itself. The reporting cells scheme is global because all mobile terminals perform their location updates in the same set of reporting cells, and it is static because the reporting cells are fixed. The set of reporting cells should be selected such that the total location management cost is minimized. Many methods have been proposed to find the set of reporting cells. In Subrata and Zomaya 2003, the authors proposed three

Figure 2: Relationship between reporting cells and location areas

artificial life techniques including genetic algorithm, tabu search, and ant colony algorithm to identify the set of reporting cells.

Although the location areas scheme seems completely different from the reporting cells scheme, a method is proposed to derive the location areas from a set of reporting cells (Wang, Fan, and Zhang 2002; Wang and Zhang 2005). Figure 2 shows four location areas A, B, C, and D derived from four reporting cells. Basically, all the contiguous non-reporting cells form a location area. A reporting cell can form a location area by itself or can belong to a neighboring location area, depending on the amount of traffic going in and out the reporting cell. It is also observed that the location update cost difference is small between the original reporting cells scheme and the derived location areas scheme, whereas the paging cost in the original reporting cells scheme is larger than that in the derived location areas scheme. This is mainly because there is no overlapping between two location areas, and yet the vicinity of one reporting cell could overlap with vicinity of another reporting cell. Simulation has been done to verify the observation in both aggregate and individualized mobility models.

INDIVIDUALIZED AND DYNAMIC SCHEMES

A global scheme is usually static. In a global and static scheme, a subset of cells bears the burden of all location update signaling. For example, in the location areas scheme, all location updates are performed in the boundary cells between two location areas and no location updates occur in an interior cell. This causes disparity among cells in terms of location update signaling. To address this issue, many individualized and dynamic schemes have been proposed. The most classical ones are time-, movement-, and distance-based (Bar-Noy, Kessler, and Sidi 1995). In the time-based scheme, a mobile terminal updates its location every T units of time for a given time threshold T . In this way, location updates can occur in any cell. The corresponding paging strategy for the one-dimensional network topology is described as follows (Bar-Noy, Kessler, and Sidi 1995): when a call arrives for a mobile terminal, the cellular network first searches the cell last reported by the

mobile terminal, say i . If the mobile terminal is not found there, the network searches the cells at distances j from i , with j starting with 1 and the process continues until the mobile terminal is found.

In the movement-based scheme, each mobile terminal maintains a counter that keeps track of the number of cell boundaries it has crossed since its last location update. The counter is initialized to zero after each location update. Whenever the mobile terminal moves out of the current cell and enters a neighboring cell, it increases the counter by one. When the counter exceeds a predefined threshold, say M , the mobile terminal updates its location and reset the counter to zero. When an incoming call arrives for a mobile terminal, the cellular network will page all the cells within a distance of M from the last-reported cell. Figure 3 illustrates the movement-based scheme with $M = 3$. It is assumed that the mobile terminal updates its location and resets the movement counter to zero at cell O. When the mobile terminal moves from cell O \rightarrow A \rightarrow B \rightarrow C \rightarrow D, its movement counter increases from $0 \rightarrow 1 \rightarrow 2 \rightarrow 3 \rightarrow 4$. Therefore when the mobile terminal enters cell D, it needs to report cell D as its current location, reset the movement counter to zero, and start a new iteration. If there is a phone call for the mobile terminal before it enters cell D, all the cells in the figure have to be paged. In Casares-Giner and Mataix-Oltra 1998, the authors enhanced the movement-based scheme by resetting the counter to zero when a mobile terminal moves back to the last-reported cell. It is shown that the enhanced version reduces the location update cost significantly with a slightly increased paging cost.

In the distance-based scheme, a mobile terminal keeps track of the distance between the current cell and the last-reported cell. The distance between two cells is the minimal number of cell boundaries that need to be crossed from the source cell to reach the destination cell. When the distance exceeds a predefined threshold, say D , the mobile terminal updates its location. When an incoming call arrives for a mobile terminal, the cellular network pages the mobile terminal in all the cells that are within a distance of D from the last-reported cell. The distance-based scheme with $D = 3$ is illustrated in Figure 3; again it

Figure 3: Comparison of movement- and distance-based schemes

is assumed that the mobile terminal updates its location at cell O. Unlike the movement-based scheme, a mobile terminal does not need to update its location as long as it stays within the cells in the figure. As with the movement-based scheme, if there is an incoming call for the mobile terminal before a new location update, all the cells in the figure have to be paged. It seems intuitive to think that the distance-based scheme would perform better than the movement-based scheme. In Bar-Noy, Kessler, and Sidi (1995), the authors have shown that the distance-based scheme performs significantly better than the time-based and movement-based schemes in both memoryless and Markovian memory movement patterns. However, it has been claimed that it is hard to compute the distance between two cells or that it requires a lot of storage to maintain the distance information among all cells (Akyildiz, Ho, and Lin 1996; Li, Kameda, and Li 2000). In Nocetti, Stojmenovic, and Zhang 2002, it is shown that, if the cell IDs can be assigned properly, the distance between two cells can be computed very easily. Specifically, the authors proposed two three-component cell address forms, i.e., the shortest-path form and the zero-positive form.

In the time-based scheme, sequential paging is used. If the simultaneous paging is required, the cellular network has to know the paging radius. To address this issue, the time-based scheme is extended in Zhang 2000. In addition to keeping the elapsed time, the scheme in Zhang 2000 also keeps track of the maximal distance traveled since last update. When it is time for location update, the mobile terminal reports both its current cell and the traveled maximal distance that can be used later as the paging radius. A mobile terminal performs its location update either when the timer expires or when the traveled maximal distance exceeds the last-reported maximal distance. The scheme is a combination of the time-based and distance-based schemes.

The dynamic location management scheme proposed in Naor 2000 is also based on both time and distance. Specifically, both the cellular network and the mobile terminal keep a look-up table that consists of a distance row D_1, D_2, \dots, D_k and a time row T_1, T_2, \dots, T_k . The table describes the relationship between the distance and the time: the distance decreases while the time increases. That is, $D_1 > D_2 > \dots > D_k$ and $T_1 < T_2 < \dots < T_k$. A mobile terminal updates its location if the distance it has traveled exceeds D_i , when time T_i has elapsed since the last update. Therefore, if a mobile terminal has not performed any location update when time T_i has elapsed, the mobile terminal is within a distance of D_i from the last-reported cell. In this case, when an incoming call arrives for the mobile terminal, the cellular network only needs to page the mobile terminal in all the cells that are within a distance of D_i from the last-reported cell. The nice feature of this scheme is that, if the mobile terminal has not updated its location when time elapses, the paging area for the mobile terminal automatically becomes smaller. Therefore, the paging cost is reduced without any additional location update cost. Performance analysis shows that the look-up table based scheme performs better than the time-based, distance-based, and location areas scheme.

The look-up table based scheme in Naor 2000 works very well with a mobile terminal traveling at a low speed.

At a low speed, a mobile terminal cannot travel the corresponding distance when a specified time elapses. In this case, the mobile terminal does not need to update its location, and the paging area will be small when there is an incoming call for the mobile terminal. However, the scheme does not perform well when the incoming call arrival rate is high or when the traveling speed of a mobile terminal is high. To address these two issues, the authors in Wang and Zhang 2002 proposed to use an enhanced look-up table that consists of two parts. The distance in the first part increases while the time increases, and as in the original look-up table, the distance in the second part decreases with increasing time. By introducing the first part of the table, the paging cost for a call arriving shortly after a location update will be greatly reduced. Numerical simulation shows that the enhanced look-up table based scheme performs well for mobile users traveling at a high speed as well as for those traveling at a low speed.

CALL-ARRIVAL-RATE AND MOBILITY-BASED SCHEMES

In the location areas scheme, when an incoming call arrives for a mobile terminal, the cellular network will page for the mobile terminal within its last-reported location area. However, a location area is usually large, and a mobile terminal normally moves only among a fraction of cells in the location area (Rose and Yates 1995). If the mobility of a mobile terminal is known, there is no need to page all the cells in the location area; this leads to reduction in the paging cost. Similarly, the call arrival rate can affect the design of a location management scheme. If the probability is low that a mobile terminal will receive a call, it is a waste of wireless bandwidth to ask the mobile terminal to keep updating its locations. Therefore, a good location management scheme should take advantage of the mobility and the call arrival rate of individual subscribers.

The call arrival rate and mobility of a subscriber are used to dynamically decide the size of location areas for that individual subscriber in Xie, Tabbane and Goodman 1993. Analysis results show that the proposed dynamic scheme uses significantly less signaling bandwidth than the fixed location areas scheme when the call arrival rates are user-variant or time-variant. Furthermore, without fixed borders of location areas, the proposed scheme allocates the signaling burden of location updates more evenly. In Akyildiz and Ho 1995, the mobility pattern and the incoming call arrival probability of a mobile terminal are used to decide whether it needs to update its location. Whenever a mobile terminal enters a new cell, it computes the paging cost if it does not perform a location update. The weighted paging cost, i.e., the paging cost multiplied by the call arrival probability, will be compared with the cost of one location update. A location update will be performed if the weighted paging cost is more than the cost of one location update.

A selective location update strategy was introduced into the location areas scheme in Sen, Bhattacharya, and Das (1999). The idea is that if a mobile terminal has little chance of receiving a call while within a location area either because it remains there for a very short time or

it has an extremely low probability of receiving a call, then wireless bandwidth would be wasted by performing a location update. In the scheme presented by Sen, Bhattacharya, and Das, a mobile terminal updates its location only at a subset of location areas, called update areas. The corresponding paging cost will be higher because the cellular network needs to track down a mobile terminal's current location area from the last-reported location area. To determine the update areas, a genetic algorithm is used to optimize the total location management cost.

Semi-real-time velocity information about a mobile terminal is used in Wan and Lin 1999 with either the movement- or distance-based scheme to dynamically compute the paging zone for an incoming call. If only the magnitude of the velocity is used, the resulting paging zone is a smaller circular area; if both magnitude and direction are used, then the resulting paging zone is an even smaller sector. The analysis and simulation results of Wan and Lin show that their schemes have a significantly lower cost than the standard location areas scheme.

In the distance-based scheme, the cellular network locates a mobile terminal by paging the cells around the last-reported cell. This works well if the mobile terminal follows the random walk mobility model. In Liang and Haas 1999, the authors argued that the Gauss-Markov mobility model is more realistic than the random walk mobility model. The Gauss-Markov mobility model is then used to predict the future cell of a mobile terminal. The mobile terminal updates its location if it reaches some threshold distance away from the predicted cell. When an incoming call arrives for the mobile terminal, the cellular network pages the cells around the predicted cell instead of the last reported cell. The simulations demonstrate the performance advantage of the predictive distance-based scheme over the regular distance-based scheme. In Tsai and Jan 1999, the authors proposed a look-ahead strategy to be used with the distance-based scheme. The look-ahead strategy uses a multi-scale, straight-oriented mobility model, referred to as normal walk, to compute the optimal future cell. The optimal future cell is reported at location update instead of the current cell. The analysis of Tsai and Jan shows that the look-ahead strategy effectively reduces the tracking cost for mobile subscribers with large mobility scales.

A subscriber profile is used to dynamically create location areas for each subscriber (Scourias and Knuz 1997). A subscriber profile describes the subscriber's average duration of stay in each cell, and the number of transitions the subscriber has made from cell to cell. When a mobile terminal enters a cell that is not in its current location area, a location update is performed and a new location area is created from the new cell and the profile. First, the new cell will be in the new location area. Then the cells that were visited frequently from the new cell, referred to as the neighbor ring of the new cell, will be added to the new location area in order of decreasing frequency. Once the first neighbor ring of the new cell has been added, the above process is repeated using the newly added cells, and the process is repeated again until the location area is full or there are no more cells to be added. When an incoming call arrives for the mobile terminal, cells in the current location area with above-average duration of stay

will be paged first. If the first attempt fails, all the cells in the current location area will be paged. Their experiments using an activity based mobility model show that the profile-based dynamic location area scheme significantly outperforms the fixed location areas scheme.

In the LeZi-Update scheme proposed in Bhattacharya and Das (1999), a mobile terminal reports a new path of location areas traveled instead of a new location area, and a dictionary is used to store all the traveled paths. The dictionary, in fact, is the subscriber profile maintained by both the subscriber and the cellular network. Initially, the dictionary is empty, and a path will be reported if and only if there is no such path in the dictionary. Therefore, every proper prefix of the reported path is in the dictionary. The dictionary is stored as a trie, and the path to be reported can be encoded as the index of the largest proper prefix plus the last location area. Therefore, the location update cost is not significantly increased compared to the location areas scheme. When an incoming call arrives for the mobile terminal, the cellular network will use the trie and the last-reported path to figure out all possible paths and therefore all possible location areas for the mobile terminal. A blending weight vector is used to compute the blended probability of every possible location area. Those location areas can then be paged in order of decreasing blended probability.

PING-PONG-EFFECT REDUCTION SCHEMES

In the location areas scheme, location areas are fixed. If a mobile subscriber lives near the boundary between two location areas, there will be excessive location updates when the mobile subscriber moves back and forth between two neighboring location areas. This phenomenon is called the ping-pong effect. Besides the regular ping-pong effect, there is another kind of ping-pong effect, referred to as the generalized ping-pong effect that occurs around a corner. A corner is the intersection of three different cells that belong to three different location areas. When mobile terminals move around a corner, excessive location updates also occur. Figure 4 illustrates regular and generalized ping-pong effects. In the left figure, the regular ping-pong effect happens when a mobile terminal keeps moving between *A* and *B* that belong to two different location areas. In the right figure, the generalized ping-pong effect occurs when a mobile terminal moves

around *A*, *B*, and *C* that belong to three different location areas. In Fan, Stojmenovic, and Zhang 2002, it is shown that this regular ping-pong effect could account for 14% of the total location update cost, and the generalized ping-pong effect could account for 7% of the total location update cost. Several location management schemes have been proposed to reduce or eliminate the ping-pong effect. Some of them are also able to reduce or eliminate the generalized ping-pong effect.

In the location areas scheme, the most recently visited location area is recorded in a mobile terminal. In the two location scheme, a mobile terminal memorizes two most recently visited location areas instead of one (Lin 1997). When the mobile terminal enters a new location area, it checks whether the new location area is in the memory. If the new location is in the memory, no location update is necessary. Otherwise, the most recently visited location area will be kept and the other location area will be replaced by the new location area. Consequently, a location update is needed to report such a change to the cellular network. When a mobile terminal moves back and forth between two location areas, both location areas are memorized and no location updates are needed. Therefore the regular ping-pong effect has been eliminated. However, the two location scheme cannot eliminate the generalized ping-pong effect because the mobile terminal cannot memorize all three location areas around a corner. To eliminate the generalized ping-pong effect, something like a three location area scheme is needed.

In the location areas scheme, two location areas are non-overlapping in terms of cells. In the overlapping location area scheme (Gu and Rappaport 1999), two neighboring location areas can be overlapping, and the boundary cells of a location area can belong to more than one location area. Assume a mobile terminal moves out of cell *A* and enters cell *B* that belongs to a new location area. Due to the overlapping nature of the location areas, cell *B* is not a boundary cell of the new location area. If the mobile terminal moves back to cell *A* from cell *B*, it is still in the new location area. Therefore no location update is needed, and the regular ping-pong effect is eliminated. However, if the degree of overlapping between two location areas is small and the mobile terminal moves back multiple cells, a location update is still possible. One solution is to make the area of overlapping large, which also eliminates the generalized ping-pong effect. To make the area of overlapping large, the location areas themselves must be large, which leads to a high paging cost.

To reduce the ping-pong effect, the authors in Chung, Choo and Youn (2001) proposed a location update scheme using a virtual layer, referred to as the virtual layer scheme. The scheme places a virtual layer of location areas on the original location area layer such that each original location area will be covered by three virtual location areas, and vice versa. In the scheme, each cell belongs to two location areas. One is in the original layer and the other is in the virtual layer. If a mobile terminal leaves a location area in the original layer by moving from cell *A* to cell *B*, it will enter a new location area in the virtual layer instead of the original layer. The placement of the two layers guarantees that cell *B* will not be at the boundary of the new location area in the virtual layer. When the

Figure 4: Regular and generalized ping-pong effects

Table 1: Ping-Pong-Effect Reduction Schemes

Scheme	Regular Ping-Pong Effects	Generalized Ping-Pong Effects
Two Location (Lin 1997)	Eliminated	
Overlapping Location Area (Gu and Rappaport 1999)	Eliminated	Eliminated if overlapping is large
Virtual Layer (Chung, Choo, and Youn 2001)	Reduced	
Triple-layer (Fan, Stojmenovic, and Zhang 2002)	Eliminated	Eliminated
Multiple-layer (Fan and Zhang 2004)	Eliminated	Eliminated

mobile terminal moves back to cell *A* from cell *B*, it is still in the same location area of the virtual layer. Therefore, no location update is needed. It is shown that the virtual layer scheme can significantly reduce the regular ping-pong effect. However, the virtual layer scheme cannot completely eliminate the regular ping-pong location updates. Sometimes it may introduce more ping-pong location updates at the intersection point made by the two boundaries from two different layers. The intersection point cannot be completely covered by a third location area. The virtual layer scheme is not able to eliminate the generalized ping-pong effect either.

To eliminate both the regular and generalized ping-pong effects, a triple-layer location management scheme is proposed in Fan, Stojmenovic and Zhang (2002). Three layers of location areas are placed properly such that any boundary or corner in one layer will be completely covered by a location area of another layer. In the triple layer scheme, each cell belongs to three location areas in three different layers. If a mobile terminal moves out of the location area of the current layer, it could register with any of two location areas in the other two layers. The mobile terminal chooses the layer whose corresponding location area center is closer to the mobile terminal. Therefore, location update will not be immediate. Simulation results have shown that the triple-layer scheme performs better than the two location scheme, the overlapping scheme, and the virtual layer scheme in reducing ping-pong effects.

A multi-layer location management scheme is a generalization of the triple-layer scheme (Fan and Zhang 2004). A multi-layer scheme is referred to as the k -layer scheme if a total of k layers are employed. In the k -layer scheme, any cell belongs to k location areas, each of which is in a different layer. If a mobile terminal moves out of the location area of the current layer, it could register with any of the other $k-1$ location areas of the corresponding $k-1$ layers. To keep the mobile terminal away from the boundary in the new location area, the mobile terminal will choose the layer whose corresponding location area center is closer to the mobile terminal. It is shown the multi-layer scheme bridges the static location area scheme and the dynamic distance-based scheme. Although increasing the number of layers reduces the location update cost, the difference will be very small after the saturated number

of layers is reached. Table 1 summarizes how these schemes eliminate or reduce the regular and generalized ping-pong effects.

SELECTIVE PAGING SCHEMES

In the current location areas scheme, to locate a mobile terminal within a location area, all the cells within the location area are paged simultaneously. The paging cost will be the maximum, and it is in proportion to the number of cells in the location area. If the paging delay is not constrained, the cells in the location can be paged sequentially until the mobile terminal is found. This will greatly reduce the number of cells to be paged, thereby reducing the paging cost. It is obvious that the paging strategy mentioned earlier in the time-based scheme (Bar-Noy, Kessler, and Sidi 1995) has no constrained paging delay.

The paging delay is an important QOS (Quality of Service) metric in location management. The paging delay cannot be arbitrarily large. If the paging delay is large, the caller may perceive the delay. In addition, if the paging delay is large, a mobile terminal may move out of the current cell or even the current location area during the paging process. In general, there is a trade-off between the paging cost and the paging delay. If all the cells have to be paged simultaneously, the paging cost reaches the maximum, whereas the paging delay is the minimum. On the other hand, if there is no constraint on the paging delay, the cells can be paged sequentially in order of decreasing probability, which leads to the minimal paging cost. Therefore, many researchers proposed selective paging schemes to minimize the paging cost under an acceptable delay constraint. Figure 5 illustrates paging with no delay and with a constrained delay. In the left figure, no delay is allowed and all the cells have to be paged simultaneously. In the right figure, four page cycles are allowed, and all the cells are divided into four rings named from Ring 0 through Ring 3. A cell is in Ring n if and only if the cell has a distance of n from the last reported cell. The four rings will be paged sequentially, and the paging process stops whenever the mobile terminal is located.

Given a probability distribution on user location, the relationship between the paging delay and the paging cost were formally studied in Rose and Yates 1995. It is shown that the optimal paging strategy that minimizes

Figure 5: Paging with no delay and with a constrained delay

the expected number of locations paged is to page each location sequentially in order of decreasing probability. Because the paging delay resulting from sequential paging can be unacceptably large, Rose and Yates also consider the problem of minimizing the paging cost under constraints of the paging delay. It is also shown that if a moderate average paging delay is acceptable, the average paging cost to locate a mobile user can still be significantly reduced.

A dynamic selective paging strategy was introduced into the location areas scheme in Abutaleb and Li (1997). The goal is also to minimize the paging cost, subject to a constraint on the paging delay. If m is an acceptable paging delay, a location area will be partitioned into m partitions. Based on the mobility pattern and call arrival rate of the mobile subscriber, the partitions of the location area are computed such that the average number of cells paged are minimized. When an incoming call arrives, the cellular network pages the partitions sequentially until the mobile subscriber is located.

The selective paging strategy was studied with the movement-based scheme (Akyildiz, Ho, and Lin 1995). In the movement-based scheme, when an incoming call arrives, the cellular network pages the called mobile terminal within its residing area, i.e., all the cells that have a distance below the movement-threshold to the last-reported cell by the mobile terminal. That is, the paging is done within one polling cycle. However, if more than one paging cycle is allowed, the authors propose to apply a selective paging strategy in which the residing area of the called terminal is partitioned into a number of subareas, and then each subarea is polled, one after another, in order of decreasing probability until the called mobile terminal is located. It is shown that if the paging delay is increased from one to three polling cycles, the total location update and paging cost is reduced to the midpoint between the maximum and the minimum. It is shown that although increasing the allowable paging delay reduces the total cost, a large paging delay does not necessarily translate into a significant total cost reduction. Similarly, the selective paging strategy was applied to the distance-based scheme (Ho and Akyildiz 1995). The result shows that the reduction in the total cost of location update and paging is significant even for a maximum paging delay of two polling cycles.

It is also shown that in most cases, the average total costs are very close to the minimum when a maximum paging delay of three polling cycles is used.

In the predictive distance-based scheme (Liang and Haas 1999), the future cell of a mobile terminal is predicted, and the mobile terminal performs a location update whenever it reaches some threshold distance (referred to as the update distance) from the predicted cell. When an incoming call arrives, the cellular network pages the mobile terminal starting from the predicted cell outwards, in a shortest-distance-first order, until the mobile is located. The scheme does not deal with the paging delay. If the paging delay is imposed, it is not hard to evenly divide all possible rings around the predicted cell, and page the divisions from the inside outwards.

CONCLUSION

The personal communication system uses a cellular network as its infrastructure. In a cellular network, a service coverage area is divided into cells, each of which is served by a base station. When an incoming call arrives for a mobile terminal, the network needs to know the exact cell location of the mobile terminal so the call can be routed to the corresponding base station. Location management keeps track of mobile terminals. This is accomplished using two basic operations: location update and paging. When an incoming call arrives for the mobile terminal, the network performs the paging operation to find the cell in which the mobile terminal is located. The number of cells to be paged usually depends on how frequently the mobile terminal performs the location update operation.

The current cellular network uses the location areas location management scheme. Although simple, the location areas scheme has a lot of weak points. This chapter identified these weak points and discussed the schemes to eliminate or reduced these weak points. The location areas scheme is global and static. In a global and static scheme, a subset of cells bears the burden of all location update signaling. This chapter has reviewed several individualized and dynamic schemes that are able to more evenly distribute the signaling burden of location updates. In the location areas scheme, a location update is performed whenever the mobile terminal enters a new location area,

regardless of the call arrival rate of the mobile terminal, and all the cells in the last-reported location area need to be paged regardless of the mobility of the mobile terminal. This chapter introduced some mobility and call arrival rate based location management schemes. In the location areas scheme, the ping-pong effect (i.e., an excessive number of location updates) exists when mobile terminals move back and forth between two neighboring location areas. This chapter discussed several location update schemes to eliminate or reduce the ping-pong effects. Again in the location areas scheme, all the cells in the last-reported location area are paged simultaneously. This chapter discussed selective paging schemes that minimize the number of cells to be paged within a constrained paging delay.

ACKNOWLEDGMENT

The authors thank Professor Hossein Bidgoli and five anonymous referees for their constructive comments and suggestions that greatly improved the quality of this chapter. The authors also thank Li Gao of the University of Alabama for drawing the figures in this chapter. This research is partially supported by NSERC.

GLOSSARY

- BS (Base Station):** A fixed station in the cellular network that connects mobile stations to the backbone network, such as the public switched telephone network.
- Call-arrival-rate:** The number of phone calls received per unit of time.
- Cell:** The area covered by a base station.
- Cellular Network:** A network that divides a geographic area into cells to reuse the radio frequency allocated for cellular communications.
- HLR (Home Location Register):** An MSC database that stores information about the users who consider the area covered by the MSC as their home.
- Location Areas:** A location management scheme that divides the coverage area into location areas, each of which consists of contiguous cells.
- Location Management:** A subject that deals with how to track a mobile station when the mobile station is not in a call.
- Location Update:** Signals sent by a mobile terminal to the personal communication system to report its current location.
- MS (Mobile Station):** A station in the cellular network that can communicate with base stations via radio even if it is in motion. It is also called a mobile terminal.
- MSC (Mobile Switching Center):** The switching center that interconnects cellular phones with the land telephone network.
- PCS (Personal communication systems):** The system designed for wireless communications using the 1900MHz band.
- PSPDN (Packet Switched Public Data Network):** A network that divides the data into packets to be transported individually within the network.
- PSTN (Public Switched Telephone Network):** The regular wireline telephone network.

Paging: Signals sent from the personal communication system to locate a mobile terminal when a phone call is made to it.

Ping-pong-effect: A phenomenon of excessive location updates when the mobile subscriber moves back and forth between two neighboring location areas.

Selective Paging: A strategy to divide a paging area into several regions based on a certain criterion and to page these regions sequentially or selectively instead of simultaneously to reduce the paging cost.

VLR (Visitor Location Register): An MSC database to temporarily store information about the subscribers who are visiting the area covered by the MSC.

INTRODUCTION

As a result of the development of communication technologies, a variety of wireless networks have been deployed worldwide. The third-generation (3G) networks, including code division multiple access 2000 (CDMA2000) and the universal mobile telecommunications system (UMTS), support both voice and data traffic from 144 kbps to 2.4 Mbps. They constitute the backbone of future wide area networks (WANs). In the meantime, technologies coming along the evolutionary path (e.g., global system for mobile communications [GSM], interim standard 95 [IS-95], general packet radio service [GPRS], and code division multiple access 1x [CDMA1x]) will coexist for a long time. The Institute of Electrical and Electronics Engineers (IEEE) 802.16 Working Group creates standards for broadband wireless access, Worldwide Interoperability for Microwave Access (WiMAX), in metropolitan area networks (MANs) with a scalable solution to extend fiber optic backbones.

IEEE 802.16 supports point-to-multipoint data transmission at rates up to 134 Mbps.

The interest in wireless local area network (WLAN) technology has surged in recent years due to its low cost and high data rates. WLAN systems are widely deployed in hotspot locations, such as airports, hotels, and coffee shops, as well as in business enterprises and homes. WLAN has developed many versions, including 802.11a, 802.11b, 802.11h, 802.11i, 802.11n, and so forth. These technologies can provide relatively high-speed communication (up to 540 Mbps in 802.11n) but limited coverage area. The UWB 802.15 family technologies can even provide Gbps speed in personal area networks (PANs). These networks may have overlapping coverage areas and different cell sizes, ranging from a few meters to tens of kilometers as shown in Figure 1. Some technologies complement one another and may compete for market shares. This naturally calls for integration in terms of authentication, billing,

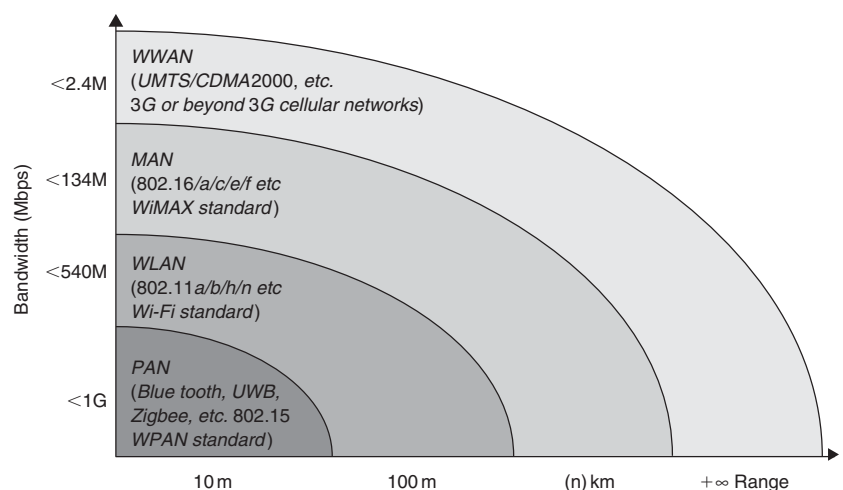

Figure 1: Wireless networks range-to-speed plot

roaming, mobility, and quality of service (QoS) among all of these technologies. Mobility management issues in such a heterogeneous environment have become a hot research topic, aiming to enable users to move around while staying connected and receiving calls, data streams, and other services.

The mobility issue is accompanied by the development of wireless local area networks. In 1971, the first WLAN prototype, composed of seven computers, was deployed by the University of Hawaii. In 1990, following three generations of development, the IEEE 802 Executive Committee established the 802.11 Working Group to standardize the WLAN. In the meantime, in the early 1990s, GSM/CDMA offered a 9.6 kbps data-service standard. The vertical mobility concept was first introduced by the BARWAN project at the University of California–Berkeley to deal with global roaming. Since then, the research and development of mobility management schemes has been very active. Currently, intensive efforts are being made to address the mobility issues among some specific interfaces. Mobility issues will be raised mainly in the following three circumstances:

Network availability—The network situation changes from time to time as a result of interference, equipment noise, and multipath loss factors. The serving access point (AP) may fall out of service due to certain errors. The terminal should have the ability to transit connections in overlay networks.

Client moving—The mobile node (MN) moves away from an AP and enters into a new AP, or roams from one network to another network in overlay networks.

Load balancing—MN may be switched to a neighboring AP in order to reduce the load on the current AP and guarantee QoS.

Terminal devices must be capable of automatically detecting multiple-access networks in order to support seamless transition from one network to another. Mobility management has two major functions: location management and handoff management (Akyildiz et al. 1999). Location management keeps track of the position information of the MN through the registration and paging processes. Authentication is usually done in the registration process. The paging area depends on the network topology and design. The size of the paging cluster should not be too large or too small, to avoid unnecessary system overhead. The handoff management process allows the MN to stay connected while moving around the overlay networks. These two functions will interact instead of standing alone in modern mobility management schemes; for example, the location process can assist handoff decisions.

There are two types of handoff mechanisms: horizontal handoff and vertical handoff. The former refers to the movement among different access points in the same network interface, which is also called intra-system handoff. Horizontal handoff is theoretically easier to handle. Vertical handoff often refers to the movement under different technologies or network systems, which is also called intersystem handoff. For instance, when an MN moves from a WLAN hotspot to 3G networks, vertical handoff

takes place to support seamless service transition. For the purposes of our discussion, a domain refers to a cluster of certain subnetwork elements. Micromobility essentially involves intradomain handoffs in which the MN is handled without external coordination. Macromobility involves moving between two domains that may belong to different types of networks or organizations.

In comparison to macro- and micromobility, the terminology of *horizontal* and *vertical* reflects the wireless access network technology change instead of the domain-based subnetwork change. Therefore, there are subclasses such as vertical macromobility, horizontal vertical macromobility, vertical micromobility, and horizontal micromobility (Akyildiz, Xie, and Mohanty 2004). Regardless of the mobility model, the handoff decision can be made on either the terminal or network side. If the handoff is totally decided by the terminal side, it is called mobile-controlled handoff; if the handoff is decided by the network side, it is called network-controlled handoff. In some systems, the terminal provides some measurements to the network, and the network executes the handoff. This is called a mobile-assisted handoff mechanism.

Many mobility solutions have been proposed to support both macro- and micromobility, either in homogeneous or heterogeneous circumstances. The idea is to achieve a trade-off between QoS, efficiency, and latency requirements. The issue of cost in terms of additional network infrastructure to implement these solutions will also affect the application of these protocols. The handoff latency should be reduced to as small as possible. Once the handoff begins, the process is expected to complete efficiently. Here, efficiency refers to less signaling traffic and fewer unnecessary handoffs. The quality of service is becoming a more and more important factor that needs to be evaluated with the development of multimedia applications. It is, of course, ideal to meet all criteria for a scheme; in reality, these factors must usually balance against one another. For example, the tolerance of short interruption will lead to lower latency and higher efficiency. Figure 2 illustrates the trade-off among the influencing factors. Compromised solutions are generally looked for inside the

Figure 2: Influencing factors tradeoff

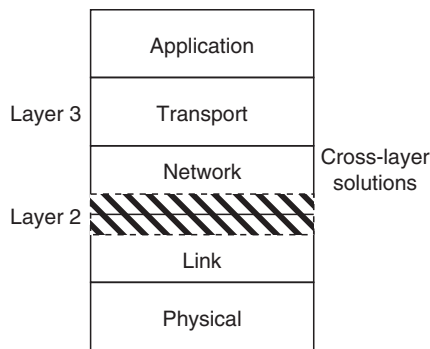

Figure 3: Network layers for mobility

gray area, which can satisfy all the criterias of QoS, latency, and efficiency.

Currently there are various mobility management schemes aimed at different network layers, including the data-link layer, network layer, and transport layer. Eddy (2004) attempts to answer the question of which layer should handle mobility, focusing on the properties of the layers themselves instead of a particular mobility scheme. Figure 3 presents the general five-layered architecture for wireless networks. The link layer reports link status (e.g., link up and link down) and channel conditions to upper layers, which in some cases are used to help layer-three handoff. The network layer mainly supports terminal mobility, in terms of using mobile Internet protocol (IP) techniques. The application layer supports various types of applications and interacts with lower layers. Session initiation protocol (SIP) is an application-layer solution that has been enhanced to support mobility. Based on the layers in which mobility functions reside, mobility solutions can be classified as link-layer protocols, network-layer protocols, transport-layer protocols, application-layer protocols, and cross-layer protocols. This chapter will introduce each of these layers in a bottom-up manner.

The rest of the chapter is organized as follows: The following three sections present mobility management solutions based on their functioning layers. Most of the schemes have particular advantages and disadvantages. Cross-layer solutions, including multiprotocol label switching (MPLS) and media-independent handover (MIH) solutions are then discussed. The section that follows discusses the challenges of designing mobility management solutions, which are the principle aspects that need to be addressed in future networks. Finally, the chapter contents are summarized.

LINK-LAYER SOLUTIONS

Link-layer mobility management solutions focus on the issues related to intersystem roaming between heterogeneous access networks with different radio technologies and different network management techniques (e.g., mobility management in UMTS/WLAN or CDMA2000/WLAN interfaces). These solutions are designed to gain seamless communications in various mobility models. As a result, they are correlated to specific wireless network interfaces.

Link-layer mobility management solutions rely on the link properties of various network interfaces. These solutions focus on access network management instead of routing issues. Therefore, these solutions are usually tightly coupled with specific networks. The main target is to provide seamless, lower-latency vertical handoffs while guaranteeing the application's QoS. Seamless handover describes the capability of vertical handoffs between different networks without service interruption. A typical handoff scenario between WLAN and 3G networks is illustrated in Figure 4. The process usually includes new agent detection, authentication, registration and acknowledgement, and more. Parikh et al. (2003) proposed a seamless handoff solution from WLAN to CDMA2000 network; this scheme splits the whole handoff process

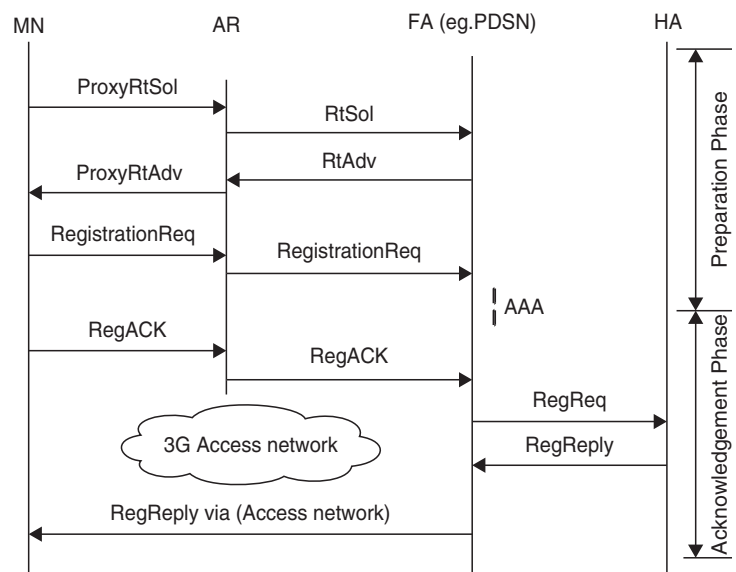

Figure 4: A typical handoff scenario between WLAN and 3G networks

into two phases—the preparation phase and the acknowledgement phase—and proactively executes the preparation phase when coming to border areas. The preparation phase includes processes of network detection, authorization to neighboring networks, getting QoS information of the applications, and so forth. This solution reaches a lower handoff latency (90 ms) than do brute force and other seamless solutions (Parikh et al. 2003). A link-layer handoff scheme needs to address two aspects of handoff issues: triggers and execution. The former refers to when to start the handoff, and the latter refers to how to execute the handoff process efficiently. G. Fan et al. (2005) further proposed a three-phased handoff scheme by introducing a pending phase to handle the gaps across WLAN hotspots. This scheme improved the handoff triggers and execution processes by differentiating the service types and considering the QoS requirements besides the receiving signal strength (RSS).

In policy-based handoff schemes (Murry, Mathur, and Pesch 2003; Wang, Katz, and Giese 1999), a set of predefined rules are used to optimize the vertical handoff trigger. A network policy engine and a client policy engine are resided on the network side and the terminal side respectively. The policy rules are like a black box whose inputs are outside events and outputs are handoff triggers. The input events may include link drop, worsening signal-to-noise ratio, QoS status change, and so forth. The inside of the box could be as simple as a priority list or as complicated as complex fuzzy logic algorithms (Vanem, Svaet, and Paint 2003; Tenhunen and Sauvola 2003). Making the policy more intelligent and adaptive based on the run-time feedback is an important research topic.

To achieve low latency, a number of fast handoff schemes have been proposed. The planning of the delay budget for seamless mobility is discussed in Alimian and Aboba (2004). The handoff delay usually comprises detection time, configuration time, and registration time (Chakravorty et al. 2003, 2004). One common idea of the fast handoff schemes is to optimize the handoff decision point by executing some preparation steps proactively prior to handover. The preregistration post-registration handover methods are proactive handoff schemes to reduce handoff latency (Network Working Group 2007). The preregistration method allows the mobile terminal to communicate with the new foreign agent (FA) while still connected to the old foreign agent. The mobile host can perform a layer-3 handover before it completes the layer-2 handover because L2 trigger is used to trigger layer-3 handoff; L2 trigger is the information from L2 that informs L3 of particular events before and after L2 handoff. The post-registration method provides data delivery to the mobile node at the new FA even before the formal registration process has completed because there is a bidirectional or unidirectional tunnel between the old FA and the new FA that allows the mobile host to continue using its old FA while on the new FA's network. A combination of the two methods has been proposed (e.g., fast router advertisement handoff, router advertisement caching, and so forth; Vidales et al. 2004). In Ylianttila et al. (2001), the proactive execution of the detection phase greatly reduced the detection and configuration time. However, the proactive execution may also result

Figure 5: Spurious handoff with Dwell Timer

in unnecessary overhead signaling. When to start the proactive steps is an issue to be carefully considered. In some special cases (e.g., a fast-moving terminal in a complicated electronic circumstance), spurious handoffs should be reduced to an acceptable percentage. This is called ping-pong effect, which causes unnecessary signaling traffic and even service disruptions. QoS requirements can be used to filter these redundant handoffs. In a QoS-assisted scheme, the QoS requirements (besides RSS) are taken into consideration. Another method to overcome ping-pong effect is to use Dwell Timer (Ylianttila et al. 2001). The signal strength must carry over the threshold within this timer before a handoff can take place. Thus, it can reduce the unnecessary handoffs caused by signal fading or a client's frequent moving. The timer should be adapted to the specific network implementation. If the timer is too long, the service may disrupt before handoff completion; if the timer is too short, it will leak spurious handoffs. Although the use of such techniques may not filter all redundant handoffs, a good design should balance these two factors and use appropriate values, as shown in Figure 5.

NETWORK-LAYER SOLUTIONS

Network-layer solutions are usually called layer-3 solutions, in which the mobility model is integrated in the IP layer. Mobile IP (MIP) technologies are used to support macro-mobility, which is defined in RFC3344 for IPv4 (Perkins 2002), and in RFC3775 for Mobile IPv6 (Perkins, Johnson, and Arkko 2003). Both versions can provide mobility management and data forwarding. In mobile IP networks, each mobile host has a permanent IP address (home address) and a care-of address (foreign address) when roaming in a foreign location. Tunnels are established between the home agent and the foreign agent; the incoming data can be routed to the correct address through this tunnel. Many MIP extended solutions are proposed to support micro-mobility more effectively, such as cellular IP, Hawaii, and hierarchical mobile IP (HMIP). The common goal among all of the architectures is to ensure that all packets can be routed correctly with lower latency, which can be summarized by two design principles: correctness and

efficiency. More detail on those protocols will be covered in the following sections.

Mobile IP

A packet is transmitted from the source to the destination depending on the destination address in the IP header. As a mobile host moves to another subnet, it must acquire a new IP address along with other necessary information. This changing of IP address usually results in interruption of services. Mobile IP was first introduced to support mobility of various wireless applications and has become an underlying technology. It allows seamless handover for mobile data applications and wireless computing.

In a mobile-IP-enabled network, there are usually four components. A mobile node (MN) is a terminal device that roams in the wireless network. The home agent (HA) is a router on the home network, which records the permanent address of an MN. The foreign agent (FA) is a router that records the MN's care of address (CoA) when it roams in a foreign network. The current MN communicates with the corresponding node (CN) through the mobile IP network. A tunnel is established between the HA and the FA. Data to the MN in a visited network are delivered via tunnel from the permanent address (HA) to the CoA. However, the basic mobile IP may result in routing inefficiencies. Packets from the mobile node are first routed to HA and then rerouted to FA through the existing tunnel in a process called triangle routing. Triangle routing leads to routing inefficiencies and aggregates the load of HA. When MN moves between different FAs, there is no direct link between those FAs. This also introduces long delays in packet delivery. Because the tunnel should be established between the FA and HA before rerouting, it cannot support high-mobility situations.

FMIPv6 (Dommety 2005) reduces latency packet loss by providing fast IP connectivity as soon as a new link is established. FMIPv6 provides preconfiguration of link information (e.g., the subnet prefix) in the new subnet while the MN is still attached to the old subnet; therefore, MN can quickly detect and connect the new subnet. This reduces the preconfiguration time in the new subnet. In addition, FMIPv6 improves the packet forwarding success rate by fixing up the routing during link configuration and binding update, so that packets delivered to the old CoA are forwarded to the new address.

Hierarchical Mobile IP

Hierarchical mobile IP (HMIP) aims to minimize the aforementioned problems in basic mobile IP technologies and improve the micromobility performance (see Gustafsson, Jonsson, and Perkins 2000; Soliman et al. 2003, 2004; Haverinen and Malinen 2000). The FAs are organized into a hierarchical structure, as illustrated in Figure 6. A mobility anchor point (MAP) is introduced for regional registration; MAP is a router in the hierarchy tree that can mimic the function of HA inside a MAP subnet. A connection is established between MAP and HA through initial registration to handle the macromobility between MAP subnets. The mobile node only needs to conduct reregistration to the MAP while moving inside the

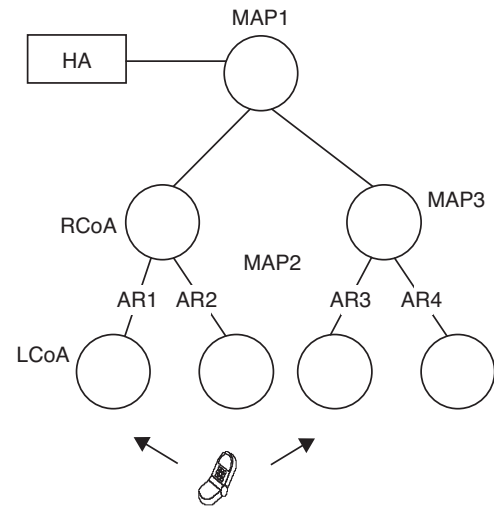

Figure 6: HMIP architecture

domain. If all the routers are directly connected to the MAP, this is called a two-level hierarchical structure. Otherwise, one MAP connects to a root MAP in a subnet that is called a multiple-level hierarchical structure. There are two types of care-of addresses: regional care-of address (RCoA) and local care-of address (LCoA). RCoA is the MAP address, and LCoA is the local AR address. Packets can be correctly forwarded to MN only using LCoA inside the subnet. Changing an attachment within a subnet will not affect RCoA. When the MN moves to a neighboring MAP subnet, the MN needs to update both the LCoA and the RCoA. The packets intercepted by the HA are first sent to corresponding MAPs using RCoA. As we can expect, the handover latency is reduced because mobility is managed locally in micromobility scenarios. The load of HA is greatly reduced because no signaling traffic exists in case of an intra-domain handover.

This hierarchical structure is also used in MIPv6 to handle micromobility issues. HMIPv6 (Soliman et al. 2003) shares the same design principle as HMIP. MAP is used to reduce the amount and latency of signaling between an MN, the HA, and the CN. The MAP acts as a local HA for the visiting mobile node by limiting the amount of signaling required outside the MAP's domain. The disadvantage of the hierarchical version of MIP is that it improves the handoff performance through scarifying routing optimization. HMIPv6 can be used together with FMIPv6 to reduce or eliminate signaling overhead and handoff delays in mobile IPv6.

Cellular IP

Cellular IP was mainly developed for mobility management in cellular networks. It inherits a number of cellular features such as paging, seamless handoff, and security management. It was first developed by Columbia University and Ericsson (Campbell et al. 2000; Valkó 1999). Each base station (BS) acts as an access point and IP router. A gateway is used to connect the cellular network to the common IP network, and the address of the gateway is used as the MN's CoA. Therefore, the incoming packets are first routed to the gateway router and then to the MN

using cellular IP function. During the routing, the location update and handoff management function are integrated in order to minimize the message overhead. The path of packets is cached so that it can be used for later forwarding. Cellular IP supports both hard handoff and soft handoff. In a soft handoff, the MN can receive messages from old BSs and new BSs simultaneously. The new connection is established before the old connection is lost so that latency and packet loss are greatly reduced. The paging function is similar to normal cellular networks; base stations are organized geographically into paging clusters. Before the first packet can be routed to the MN, the network pages the MN within the area of the paging cluster. Such a mechanism can minimize the signaling overhead and save power consumption. Cellular IP represents a new approach to IP host mobility that incorporates a number of important cellular system features such as passive connectivity, paging, seamless handoff, and so forth. For mobility between different cellular IP networks, cellular IP can work with MIP to provide macromobility capability.

Hawaii

Hawaii (handover aware wireless access Internet infrastructure; Ramjee et al. 2000, 2002) is another domain-based mobility protocol, proposed by Lucent Technologies. It extends mobile IP and addresses its limitations. Each domain has a domain root router, which is a gateway to other domains. The interdomain and intra-domain mobility are handled differently. Intra-domain mobility is handled by Hawaii, but interdomain mobility needs MIP support. Like mobile IP, each MN has a home domain and a foreign domain. When packets are sent out by a CN, they are intercepted by HA and then tunneled to the corresponding domain root router. The foreign domain root router forwards the packets to the correct path by checking the cached path entries. The mobility management function is handled by the domain root router in an intra-domain handover without interacting with HA. The domain root router updates the routing path in its cache using a path-update message. Thus, the latency and signaling overhead can be minimized for intra-domain handover. The address of the domain root router is assigned as the MN's CoA. Obviously, HA needs to update its CoA only if the MN moves to a new domain. Hawaii also differentiates the MN's idle status and active status by introducing the paging function as cellular IP. The idea behind Hawaii is not very different than cellular IP protocols.

TRANSPORT-LAYER SOLUTIONS

Transport-layer mobility is a very promising scheme with regard to overcoming various limitations imposed by network-layer schemes such as MIP. Compared with other mobility management schemes, transport-layer-based schemes have several unique advantages that motivate researchers to study them to manage mobility at the transport layer.

A great deal of research has been done on transport-layer mobility schemes (Eddy 2004; Henderson 2003; Maitz and Bhagwat 1998; Atiquzzaman and Reaz 2005;

Aydin, Seok, and Shen 2003; Chakravorty et al. 2004; Gurtov and Korhonen 2004; Huang and Cai 2005; Sarolahti et al. 2006; Schutz et al. 2005; Manner and Kojo 2004), all of which is built on a common assumption: an MN should be able to use a connection without any requirement for reconnection with the end node. As the transport layer establishes an end-to-end connection between communicating nodes, mobility schemes at this layer put the notion of mobility at the end nodes. A complete mobility management scheme consists of handoff, connection migration, and location management. In this section, the transport-layer mobility management schemes are classified and compared. The evaluation criteria include handoff, packet loss and delay, change in network infrastructure, mobility type, support for IP diversity, and more.

Mobility management in data networks involves changing the point of attachment as well as the IP addresses of an MN. A change in IP address gives rise to the challenges in maintaining an uninterrupted data flow while the MN is changing its address, minimizing loss of packets, maintaining security, identifying the newer location, and so forth. When an MN decides to detach itself from one subnet and connect to another one based on the signal strength of neighboring subnets, the MN obtains a new IP address from the new subnet. The data already in transit to the MN's old IP address may be lost, resulting in increased delay due to retransmission of the lost packets. The change in point of attachment may be confined to a single subnet or to a group of neighboring subnets. The handoff may require applications running on MN and CN to be aware of mobility, thereby reducing application transparency. Additionally, handoff between subnets—known as vertical handoff—may result in conflicts with standard network security solutions and may require additional hardware/software to be deployed in the existing network infrastructure. Based on the approach toward mobility, the current transport-layer mobility management schemes may be classified into the following categories.

Proxy-Based Protocols

A third-party device, called a proxy or gateway, is introduced and divides the TCP connection between MN and CN into two parts: MN to proxy and proxy to CN. Usually the connection between the proxy and the CN is fixed while allowing the MN to roam and change its connection with the proxy. MSOCKS (Maitz and Bhagwat 1998) uses TCP Splice for connection migration and supports multiple IP addresses for multiple interfaces. The MSOCK architecture allows mobile nodes to control which network interfaces are used for different kinds of data leaving from and arriving to the mobile nodes when changing point of attachment. Other typical methods include I-TCP, M-TCP, M-UDP, BARWAN, and so forth (Atiquzzaman and Reaz 2005).

Enhanced TCP Protocols

These protocols enhance the original TCP protocol and aim to reduce transmission delay, reduce data loss, or protect the unbroken connection. They can also add new

mechanisms to provide more complete end-to-end mobility management. Migrate and SIGMA use domain name system (DNS) for location management; Freeze-TCP and TCP-R allow a connection to be stopped and restarted before and after a handoff (Atiquzzaman and Reaz 2005). In recent years, with the increasing interest in heterogeneous network interconnection, vertical handoff has been the focus of much research effort. In general, a vertical handoff in a heterogeneous mobile wireless environment can be classified into two types: break-before-make and make-before-break (Manner and Kojo 2004). However, both approaches have their own pros and cons under different mobile scenarios. When an MN roams through different networks with various available bandwidth, the performance of TCP protocol can be highly dynamic, causing longer handoff delays due to unnecessary TCP congestions and inefficient loss-recovery processes that then make QoS provisioning in the mobile wireless environment very difficult. Therefore, several TCP enhancements for supporting vertical handoff have been proposed to tackle this problem (Chakravorty et al. 2004; Gurtov and Korhonen 2004; Huang and Cai 2005; Sarolahti et al. 2006; Schutz et al. 2005; Manner and Kojo 2004).

Other Transport-Layer Based Approaches

Stream control transmission protocol (SCTP) is a reliable message-based transport protocol developed by the Internet Engineering Task Force (IETF) that could replace TCP in some applications. SCTP allows end points to have multiple IP addresses for the purposes of fault tolerance. Some extensions based on SCTP are used for transport-layer mobility management. Mobile SCTP (mSCTP; Atiquzzaman and Reaz 2005) supports IP diversity and soft handoff. Cellular SCTP (cSCTP; Aydin, Seok, and Chen 2003) uses two primary addresses in parallel to duplicate the packet transmissions (while halving the transmission rate) during handoff to provide soft handover. R2CP and MMSP (Atiquzzaman and Reaz 2005) also belong to this category.

APPLICATION-LAYER SOLUTION

Session initiation protocol (SIP) is a signaling protocol to support real-time multimedia applications of roaming users. SIP is an application-layer control protocol that transparently supports name mapping and service redirection. Users can maintain a single externally visible identifier (e.g., an e-mail address) regardless of their network location. SIP can be used to provide means of personal, terminal, and session mobility in a mobile Internet (IETF SIP Working Group 2002). Terminal mobility is the ability of a terminal to access the network while changing its location. Personal mobility is the ability of a user to reach any available network through a per-user level ID of any type of terminal belonging to this ID. Session mobility refers to the ability of a user to maintain the same session while changing its supporting terminals.

Entities in SIP include user agents (UAs) and SIP servers. User agents are end-user devices—such as cell phones, PCs, laptops, personal digital assistants (PDAs), and

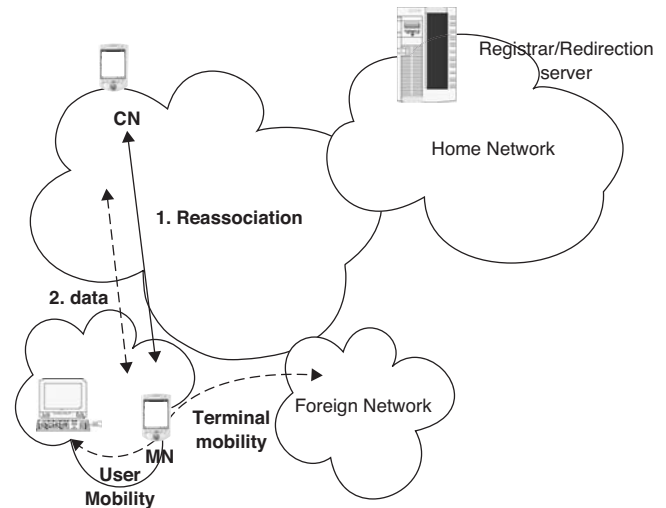

Figure 7: SIP network model

so forth—that initiate SIP sessions. SIP servers enable network operators to install routing and security policies, authenticate users, and manage user locations. There are three types of session servers: proxy server, redirection server, and registrar server. A user is identified using an email-like address: “user@host.” The session remains active when a user moves or changes communication terminals. SIP registrar servers are databases that contain the locations of all user agents within a domain. Each time the MN changes its location, the server needs to update its location information, as shown in Figure 7. This resembles the function of the home agent in MIP. If the mobile node moves during a session, it must send a new INVITE message to the CN using the same call identifier as in the original call setup. The MN tells the CN of its new IP addresses in the INVITE message. During the registration, the MN also notifies the CN of other terminal addresses for this user. When the session is moved from one terminal to another, the CN can find the correct mapping information from the registrar server; thus, the session can be correctly routed to the new terminal.

The SIP supports personal mobility in the application layer; however, the seamless and low latency requirements may not be satisfied in some cases. The SIP could be complementary techniques acting with network and link-layer mobility solutions. In order to reduce the handoff latency, the media-independent pre-authentication (MPA) scheme is proposed in Dutta et al. (2005). MPA is a mobile-assisted, secure handover scheme that works over different link-layer and network-layer protocols. Thus, it is an optimization scheme in the application layer. It shares the common motivation of fast handoff schemes to perform discovery or authentication proactively. A great deal of related research has been conducted on coordinating the SIP and MIP protocols to support the terminal mobility, personal mobility, and session mobility simultaneously (Nakajima et al. 2003; Wang, Abu-Rgheff, and Akram 2004). Interested readers can refer to related documents on the detailed implementation of these various SIP variations.

CROSS-LAYER SOLUTIONS

Multiprotocol label switching (MPLS) is a packet-forwarding technology that integrates the label-swapping paradigm with network-layer routing (Rosen, Viswanathan, and Callon 2001). In MPLS-enabled networks, each packet is assigned a label through which it can be routed by label-switching routers (LSRs) in an MPLS domain. MPLS operates between layer 2 and layer 3 in the protocol stack; thus, it is referred to as a layer-2.5 protocol. The mapping between IP and a label-switched path (LSP) is done by a forwarding equivalence class (FEC) function in each LSP. MPLS can also be integrated with mobile IP. Some variations of MPLS protocols can be used to support macro- and micromobility; these variations will be discussed later in the chapter.

Media-independent handover (MIH) is a new layer designed to support handoff in a variety of access technologies. The IEEE 802.21 Working Group is standardizing the media-access-independent mechanism in heterogeneous networks, focusing on 802 families and cellular systems. The purpose is "to improve the user experience of the mobile devices by facilitating handover whether or not they are of different media types, including both wired and wireless, where handover is not otherwise defined and to make it possible for mobile devices to perform seamless handover where the network environment supports it" (IEEE 2005). The 802.21 Working Group officially began work in this area in March 2004. A separate MIH layer between layer 2 and layer 3 is designed to support handoff in a variety of access technologies, such as 802.3, 802.11, 802.16, 3rd-Generation Partnership Project (3GPP), and 3GPP2 networks. The MIH should be supported in both the mobile terminal and the network to enable the layer-2.5 platform. A series of procedures is used to communicate between the MIH layer and data-link layers/IP layers.

MPLS Solutions

MPLS stands for multiprotocol label switching because its techniques are applicable to any network-layer protocols (Rosen et al. 2001). Each router independently chooses a next hop for the packet based on its analysis of the packet's header and the results of running the routing algorithm. A router that supports MPLS is known as an LSR, and the edge routers that assign labels to the packets are called label edge routers (LERs; Dutta et al. 2005). Several MPLS-based mobility schemes have been proposed in Kompella and Rekhter (2002), Sethom et al. (2004), Doria and Worster (2000), Choi, Kang, and Choi (2003), Kim et al. (2001), Nguyen, Li, and Xie (2003), Guo, Antoniou, and Dixit (2002), Chiussi, Khotimsky, and Krishnan (2002), Zhong et al. (2001), and Xie, Wong, and Leung (2003). The MPLS Working Group is responsible for standardizing the use of label switching and the implementation of label-switched paths over various packet-based link-level technologies, such as Packet-over-Sonet, Frame Relay, asynchronous transfer mode (ATM), and local area network (LAN) technologies. To improve scalability of generalized MPLS, it may be useful to aggregate LSPs by creating a hierarchy. Several methods for creating hierarchical MPLS structures can be found in Kompella and Rekhter (2002).

The assignment of a particular packet to an FEC is made only once as the packet enters the MPLS domain. This ensures that once a packet is assigned an FEC, subsequent routers do not need to analyze the header again.

General Switching Management Protocol

General switching management protocol (GSMP) controls MPLS-based networks (Doria and Worster 2000; Choi, Kang, and Choi 2003). Each GSMP domain consists of a GSMP controller and many MPLS routers as slaves. GSMP allows a controller to establish and release connections across the switch, add and delete leaves on a multicast connection, manage switch ports, request configuration information, request and delete reservation of switch resources, and request statistics (Doria and Worster 2000). The GSMP slaves can inform the GSMP controller of the attachment or detachment of an MN or events like link up and link down. Usually, multiple routers are controlled by a single controller. The GSMP controller stores all of the information such as routing tables, MN connection status, LSP connection information, and so forth. When a handover occurs inside the subnet, this event can be detected by the controller via LSP slaves. The controller can easily inform the old LSP to release and the new LSP to establish the path. As shown in Figure 8, when the MN moves from LSR-8 to LSR-6, the GSMP controller2 will let the LSP1 switch to LSP2 and informs LSR-7 and LSR-8 to release the connection. The HA is not involved in the handoff process; thus, the latency can be reduced. In order to support cross-controller mobility, an interface is established between the GSMP controllers. The interdomain handover can be handled using this interface. The main difference between GSMP and common MPLS networks is that the GSMP needs a third-party controller for each subnet. GSMP is a centralized, domain-based micromobility solution, whereas common MPLS is a decentralized, hop-by-hop routing mechanism.

Mobile IP and MPLS Integration

The integration of mobile IP and MPLS is important because these two roaming protocols are expected to coexist over the long term. Some selected LSRs are set up as HAs and FAs for integration purposes. Many studies have been carried out toward integration issues (see Nguyen, Li, and Xie 2003; Guo, Antoniou, and Dixit 2002; Chiussi, Khotimsky, and Krishnan 2002; Zhong et al. 2001; Xie, Wong, and Leung 2003). Nguyen, Li, and Xie (2003) propose a new framework of hierarchical IP/MPLS integration model for 3G radio access networks. The DiffServ model is chosen for the QoS differentiation model integrated with MPLS as the underlying forwarding scheme for micromobility. This common framework aims to achieve continuous QoS with efficient micromobility support. Label edge mobility agent (LEMA) is introduced to support chained LSP redirection in Chiussi, Khotimsky, and Krishnan (2002). The major advantage of this scheme is scalability because the hierarchy of the agents is created by the mobile itself based on factors such as available bandwidth, mobility pattern, and so forth. Integration schemes of mobile IP and MPLS have been proposed in Zhong et al. (2001) and Xie, Wong, and

Figure 8: GSMP network architecture

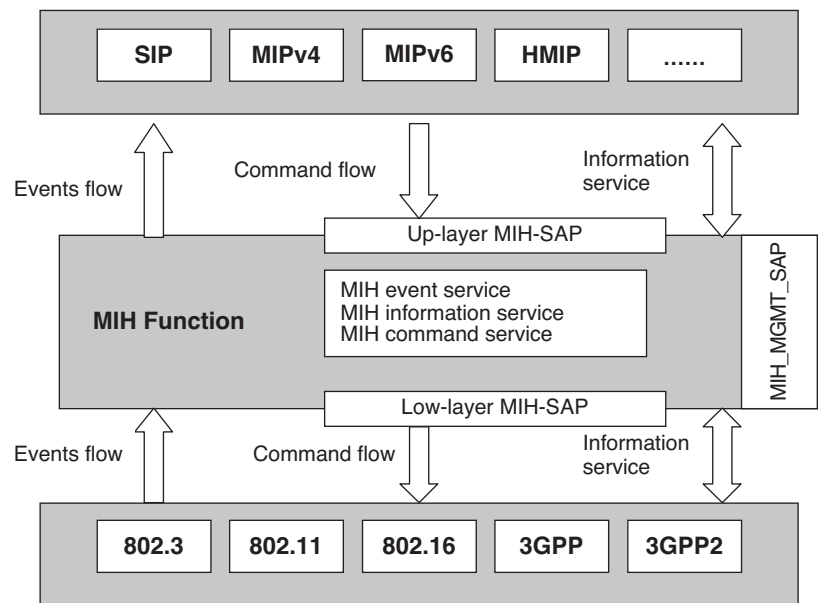

Figure 9: 802.21 reference model

Leung (2003) to improve the efficiency of mobile IP mobility support with the enhancement of features in MPLS. The HAs are freed of the burden of micromobility with MPLS-enabled gateways. Special attention is given to reduce packet loss due to handoffs in Xie, Wong, and Leung (2003) with the assistance of a MAC layer packet-recovery scheme. Each AP has a buffer through which packets can be forwarded from the old AP to the new AP. The key concept for designing the integration schemes is to establish new label-switching paths timely and efficiently with continuous QoS support, either with or without (without is usually preferable) the intervention of HAs in case of micromobility. Interested readers may refer to the corresponding literature for each of these integration models.

Media-Independent Common Platform

Existing schemes provide diverse mechanisms for detection and selection of network policies. In order to provide a common interface for supporting various mobility schemes in heterogeneous wireless networks, the 802.21

Working Group is standardizing the media-access-independent mechanism in heterogeneous networks.

The purpose of the IEEE 802.21 standard is to develop specifications that provide the upper layers with relevant network information in order to perform and optimize the handover between different heterogeneous media (IEEE 2005). The specifications include 802.3, 802.11, 802.16, 3GPP, 3GPP2, and more. MIH is a new layer that resides between the network layer (layer 3) and lower layers: MAC and physical layer protocol (PHY) or radio resource control (RRC) and link access control (LAC). Thus, it is referred to as layer-2.5 solution. This means that each existing protocol stack, both for the 802 families and the 3GPP cellular protocols, should be added with a media-independent function layer (see 3GPP TS 2006a, 2006b). The 802.21 reference model is illustrated in Figure 9. Handover occurs due to the change of user environment (e.g., a gap in radio coverage, another network is more attractive, etc.), and it is based on triggers and measurements provided by link layers of terminals (e.g., signal quality, transmission error rates, etc.). When a handoff

is going to occur; the media-independent handover function (MIHF) collects the lower-layer information and informs the upper layer, which can be used to improve or assist layer-3 handover performance.

The IEEE 802.21 architecture includes the media-independent event service (MIES), the media-independent information service (MIIS), and the media-independent command service (MICS). The MIH protocol defines the format of the messages that are exchanged between MIH entities and other layer entities. The selection of the transport mechanism depends on the access technology that connects the MN to the network. Service access points (SAPs) are collections of well-defined application programming interfaces (APIs), through which messages can be exchanged between the MIH layer and adjacent layers. The upper layers make handover decisions between heterogeneous networks (3G cellular networks, wired and wireless media in IEEE 802) by exchanging information through these SAPs. The existing upper-layer protocols can be SIP, MIPv4, MIPv6, HMIP, and so forth, and they are easy to expend whenever necessary.

The MIES provides a set of events and triggers from local and remote interfaces. The events or triggers could come from local lower layers or from peer-to-peer remote MIH functions. Events can indicate changes in state and transmission behavior of the L2 data links or predict state changes of the data-link layers. For example, the events could be "link down," "link up," "configuration change," "link event rollback," "pre-trigger (L2 handoff imminent)," and so forth. Upper layers can take corresponding action upon receiving these events.

The MIIS collects information from different access networks and provides the MIH users network information to make effective handovers. MIIS provides a set of information elements (IEs), information structure and its representation, and a query/response mechanism for information transfer. The information may include service provider information, available network information, access network information, neighbor graphs, link access parameters, location information, user authorization information, and more. The information could be stored in a separate server or in combination with other servers.

MICS refers to the commands sent from the higher layers to the lower layers in the reference model. The higher layers can use MICS to control the actions of lower layers. MICS includes the commands from the upper layer to MIH and from MIH to the lower layer, as well as commands from a peer MIH entity. These commands mainly carry the upper-layer decisions to the lower layers on local device entity or at remote entity, and thus control the behavior of lower layers. The commands are classified into two categories, MIH commands and link commands, which deal with incoming commands (from upper layer) and outgoing commands (to lower layer), respectively.

The IEEE 802.21 MIH function assists in handover decision making. Upper layers make handover decisions and link selections based on inputs and context from the MIH function. The MIH function offers a unified interface to upper layers. The service primitives exposed by the MIH function are independent of the technology-specific protocol entities of the multiple-access networks. The standard provides architecture to support transparent service

continuity between heterogeneous link layer technologies. To take advantage of the MIH function, the MN is assumed to support various access technologies, and the MIH protocol stack resides both in the network and in the terminal.

Before the end of this section, the existing schemes within various aspects (e.g., functioning layer, registration process, complexity, and standards) are compared and summarized in Table 1. The common characteristic of the techniques is that they all rely on IP technologies, which are the backbone of future networks.

CHALLENGES OF MOBILITY DESIGN

Mobility management is a key issue in providing seamless roaming in the future. We have discussed most of the major mobility management techniques in the previous sections. However, some challenges still exist with regard to the following aspects:

Smooth evolution: A wide variety of access network technologies, including cellular (2G, 2.5G, 3G), wireless local area technologies (802.3, 802.11, 802.15, 802.16, etc.) and wired access technologies, have been developed or are in development. Roaming from one access network to any other access network with different capabilities, supporting both upward smooth handoff (2G-3G-4G) and downward handoff (4G-3G-2G), is a big challenges when it comes to designing mobility management schemes. Those handoffs also require compatibility between different mobility management algorithms and modules.

Security: A user may move across different access networks; in this case, the same level of security should be guaranteed. The security management level is quite varied for different access networks with regard to authentication, authorization, and key management aspects. Mechanisms and policies, such as security mapping and separate solutions from access technologies, are needed to secure roaming on different networks.

QoS: The QoS measurements vary among different technologies. Most of them address latency, handover processing time, overhead, throughput, packet error rate, and other common characteristics. The QoS level is expected to be maintained in different mobility scenarios. QoS requirements for signaling across different network environments, such as across technology domains, are documented in Brunner (2004). However, the QoS model in heterogeneous networks is far from being solved.

Standardization: Many efforts have been made to standardize the handover interface and improve intersystem roaming capability. The 3GPP TSG SA Working Group (2006) has issued six releases toward integration, security, roaming, and framework for services issues. The IEEE 802.21 Working Group (2006) is standardizing the common cross-layer media-independent solution. IEEE 802.21 is a developing standard to enable handover and interoperability between heterogeneous network types, including both 802 and non-802 interfaces. A draft was originally released in July 2005 and

Table 1: Summary of Mobility Solutions

	SIP	M-TCP	MSOCKS	Mobile SCTP	MIP	HMIP	Cellular IP	Hawaii	W-MPLS	GSMP	Mobility-Aware MPLS	Integrated MIP/ MPLS	802.21

is still under revision. The IETF SEAMOB Working Group (2006) is focusing on special issues such as context transfer, handoff candidate discovery, and dormant mode host alerting, among others.

CONCLUSION

A main feature of future communication is that it will need to support various types of services and seamless roaming, anytime and anywhere. Mobility management is a key issue toward this goal. Great efforts have been expended on this research topic, and a number of mobility management models have recently been proposed. This chapter gives an overview on the mobility management issues in heterogeneous networks across different layers. The mobility solutions are organized in categories based on their functioning layers. SIP is a new technology that handles session mobility in the application layer. The transport-layer approaches can be used to support mobility in heterogeneous environments for TCP and user datagram protocol (UDP) connections without adding extra infrastructure. Network-layer solutions have been developed to improve handover and registration efficiency both for micro- and macromobility. The concept of domain is widely adopted in these solutions, despite the diversity of network topology. A number of link-layer solutions aim to solve the specific seamless roaming in access networks. To improve the compatibility of mobility in heterogeneous networks, cross-layer solutions (e.g., MPLS and MIH) have been explained. Finally, we discussed the challenges for mobility management and summarized important issues for future mobility design.

GLOSSARY

- GSMP:** General switching management protocol; controls MPLS-based networks.
- Horizontal handoff:** Handoffs that take place when mobile users move under different access points of the same network interface.
- MAN:** Metropolitan area network.
- MIH:** Media-independent handover; an IEEE 802.21 standard that handles the handoff in heterogeneous networks.
- MIP:** Mobile IP; an Internet engineering task force (IETF) standard communications protocol that is designed to allow mobile device users to move from one network to another while maintaining their permanent IP address.
- Mobility management:** The assigning and controlling of wireless links for terminal network connections under various kinds of mobility models. MPLS: Multi-protocol label switching; a standard from the IETF for including routing information in the packets of an IP network.
- PAN:** Personal area network.
- SIP:** Session initiation protocol; a signaling protocol for Internet conferencing, telephony, presence, events notification, and instant messaging.
- Vertical handoff:** Handoffs that take place when mobile users move under different access points in different network interfaces.

- WLAN:** Wireless local area network.
- WWAN:** Wireless wide area network.

INTRODUCTION

The evolution of telecommunication networks can be characterized by an increase in mobility functions and a solid support for a growing number of sophisticated services. The first-generation mobile wireless systems were based on analog transmission technologies with voice transmission as a unique available service. With the *second generation* (2G), digital wireless systems replaced analog systems. Digital communication not only results in better spectrum efficiency and higher quality of voice but also enables users to take advantage of new services such as *short messaging services* (SMS). The 2.5G wireless networks such as *general packet radio service* (GPRS) appeared to enhance the 2G wireless networks with best-effort packet-switched data services. However, with 2.5G wireless systems, data rates are limited to approximately 115 kbps. The goals of the *third-generation* (3G) wireless networks are to solve problems of 2G and 2.5G systems and offer wireless Internet services at a wide scale, extending the scope of 2G wireless networks from simple voice telephony to complex data applications including *voice over Internet protocol* (VoIP), video conferencing over IP, Web browsing, and multimedia services (3GPP 2001, "3G security"; Nicopolitidis et al. 2003).

Universal mobile telecommunications system (UMTS), a major 3G wireless technology, offers mobile users a large set of advantages, including: (1) new radio spectra; (2) more bandwidth; (3) security and reliability; (4) fixed, asymmetric, and variable data rate; (5) backward compatibility of devices with existing networks; and (6) enhanced multimedia services.

The *fourth-generation* (4G) systems will enable users to dynamically switch between various wireless accessing technologies to the IP-based core network. Users are expected to use different interfaces transparently and

simultaneously to access the network. Therefore, system integration is the most important enabler to the evolutionary step from 3G to 4G wireless systems.

The purpose of this chapter is to present the basics of UMTS systems, analyze their features (especially their security features), and discuss their limits. The chapter begins with a discussion of the evolution process from the *global system for mobile communications* (GSM) to UMTS. It also presents the characteristics and the architecture components of UMTS. Then it presents its *quality-of-service* (QoS) and security mechanisms. Finally, the chapter discusses the evolution toward 4G.

EVOLUTION TO 3G

GSM, a major 2G network, is evolving into 3G networks starting with the *UMTS terrestrial radio access network* (UTRA NETWORK), which is built on a 2G core network. The air interface has been changed from a system based on *time division multiple access* (TDMA) to an air interface based on *wideband code division multiple access* (W-CDMA). This modification was required to achieve 2 Mbits/s data rate connections for assignment to mobile users. UMTS offers the potential to enhance services to end users through increased bandwidth and enables the provision of more advanced data services compared to the current systems (such as SMS and multimedia messaging service). In addition to the increased bandwidth, other features in the UMTS architecture make it more attractive, including enhanced capabilities in terms of security and quality of service (Nicopolitidis et al. 2003).

In this section, we first show an evolutionary migration path from GSM to UMTS. We then compare and contrast 3G wireless technologies, focusing on their requirements and features.

UMTS Requirements

3G communication systems will enhance and extend mobility by providing anytime and anywhere accessibility, IP mobility, privacy, security of communication, and diversity of services while keeping low cost. The UMTS requirements, which were identified by the International Telecommunications Union, focus on the following items: interoperability, flexibility, service, packet-based network, fixed wireless access, fast and seamless handoff, and security.

Interoperability

UMTS must be designed to interoperate with GSM in order to facilitate the evolution from GSM to UMTS networks. Only minor modifications would be needed to enable network operators to benefit from the improved cost efficiency of UMTS while protecting their GSM infrastructures. Existing GSM and GPRS networks elements should, however, be extended to adopt UMTS QoS requirements.

Flexibility

The architecture of UMTS must be flexible to support multiple systems that are capable of offering large access to broadband mobile services anytime and anywhere. The integration of *wireless local area networks* (WLANs) to UMTS should become possible and make the heterogeneity of networks transparent.

Service

The UMTS will offer unlimited mobility and support high data rates and services with variable bandwidths and symmetric and asymmetric data transfer. This large set of services will be provided to mobile users while supporting load balancing, connection priorities, and guaranteed quality-of-service classes.

Packet-Based Network

2G wireless networks are *circuit-switched*, meaning that separate connections (or circuits) must be set up for each voice call. Packet-based networks, on the other hand, enable “always on” connections and allow multiple subscribers to receive data traffic simultaneously over the same network segment. UMTS reserves a large place to IP.

Fixed Wireless Access

UMTS network should support all types of fixed wireless access services and should be utilized for interconnecting and supplementing capacity to the fixed wired network.

Fast and Seamless Handoff

The handoff operations should be quick enough to ensure that the mobile station can receive IP packets at its new location within a reasonable period of time and so reduce the packet delay as much as possible. It also should be seamless to the mobile user and at the same time achieve efficient usage of the network resources. *Seamless* means smooth transition, such that a user does not perceive any delay or interruption of service.

Security

The mobility scheme provided by UMTS should support different levels of security requirements. In fact, security elements that have shown to be robust and useful in 2G systems should be adopted while real and perceived weaknesses must be corrected or dropped.

UMTS Key Characteristics

UMTS wireless technology is a proposed standard as a part of 3rd-Generation Partnership Project (3GPP) solutions to satisfy the International Mobile Telecommunications 2000 requirements. It is based on W-CDMA technology. The UMTS terrestrial radio access provides two modes: (1) W-CDMA FDD (*frequency division duplexing*) and (2) W-CDMA TDD (*time division duplexing*).

The specific frequencies used for UMTS are as follow.

- W-CDMA FDD: 1920–1980 MHz (uplink)
- W-CDMA FDD: 2110–2170 MHz (downlink)
- W-CDMA TDD: 1900–1920 MHz as well as 2010–2025 MHz bands

UMTS operates using 2×60 MHz bands as opposed to 2×25 MHz bands used for GSM operation (see Figure 1). One significant difference, however, is that W-CDMA has a carrier spacing of 5 MHz (resulting in just twelve carrier frequencies in each direction) as opposed to GSM, which has a carrier spacing of 200 KHz (giving it 125 different carrier frequencies). The larger bandwidth of 5 MHz is needed to support higher bit rates; the lower number of carrier frequencies is not a drawback on its capacity because each W-CDMA user is allocated the entire 5-MHz band.

The first release of UMTS specifications published by 3GPP was known as 3GPP release 99 because of a naming scheme used with GSM specifications that were released on a yearly basis. This release provides specifications concerning the UTRA NETWORK radio access network, based on the UTRA radio interface and enhancements to GSM and GPRS core networks. The following release was originally called 3GPP release 2000, but the new changes

Figure 1: UMTS spectrum

were too significant to be totally included in a single release. Consequently, release 2000 was divided into release 4, 5, 6, and 7. One key feature defined in UMTS releases 5 and 6 is high-speed downlink packet access, which offers considerably higher data capacity and data-user speeds on the downlink compared to release 99 of UMTS. This is possible through the use of a new downlink shared transport channel and a set of smart mechanisms such as a dynamic adaptive modulation and coding, a rapid scheduler, and fast retransmissions based on hybrid automatic request techniques.

In addition to the increased bandwidth, the following features planned in UMTS architecture provide enhanced capabilities in terms of quality of service and security:

- UMTS offers full coverage and mobility for 144 Kb/s, preferably 384 Kb/s for limited coverage and mobility for 2 Mbps connections. This accommodates high-speed wireless audio and video systems.
- UMTS supports the provision of innovative services such as Web browsing, instant messaging, mobile payment, and multimedia content delivery.
- UMTS provides mobile users with IP multimedia services with a guaranteed end-to-end quality of service.
- UMTS allows internetworking with GSM and GPRS systems and WLANs. Coexistence of GSM, GPRS, UMTS, and intersystem handoffs for coverage enhancements and load balancing are possible.
- UMTS allows mobile users and applications to negotiate bearer QoS characteristics.

UMTS builds on the success of the GSM system (see “UMTS Security” below). One factor that contributed to the success of GSM has been its security features. The new services introduced in UMTS require new security features to protect them. In addition, the shortcomings of GSM security need to be addressed in UMTS. The security key characteristics of UMTS are as follow.

Mutual Authentication

The mobile user and the serving network authenticate each other. In fact, each entity must prove to the other that it knows its password without actually revealing or transmitting it. In GSM, only the network can initiate authentication, which is an optional procedure, and only the mobile user is authenticated.

Signaling Data Integrity

In UMTS, signaling messages between mobile stations and a *radio network controller* (RNC) are protected by integrity code. This security feature has no equivalent

in GSM. It provides protection against false base station attacks as the origin of signaling messages required to set up a communication with a mobile can now be authenticated by the mobile.

Network to Network Security

To secure communication between serving networks, *Internet protocol security* (IPsec) can be used to provide confidentiality and integrity of communication at the IP layer. In GSM, communications in the fixed network portion are not protected.

Wider Security Scope

Security is based within the RNC rather than the base station. The confidentiality protection in GSM is located at the link layer and is always initiated by the network.

Secure International Mobile Subscriber Identity Usage

After call admission, the user is assigned a temporary *international mobile subscriber identity* (IMSI) by the serving network. This feature is the same as in GSM.

UMTS ARCHITECTURE

Wireless network evolution can be characterized by an increase in functionality and its support for a growing number of services. However, this also means that networks are becoming increasingly complex in terms of architecture. The goal of this section is to identify the key elements of the UMTS architecture and explain their interfaces.

The basic architecture of a UMTS network is divided into three components as depicted in Figure 2. These are (1) the *mobile station* (MS), (2) the *access network* (UTRA NETWORK), and (3) the *core network* (CN) (Corbett and Everit 2003). The UTRA NETWORK handles all of the functions related to radio resources and air-interface management, while the core network performs switching functions and interfaces to external networks such as the Internet or a *public switched telephone network* (PSTN).

Radio connection with mobile stations is established by means of the UMTS *Uu interface*, which is actually the W-CDMA-based UTRA radio interface. The UTRA NETWORK is connected to the transport network using the *Iu interface*; its most important feature is enabling the user to interact both with circuits and packet-based connections.

Satellite-UMTS (S-UMTS) is expected to play a complementary role to the terrestrial UMTS. In addition to its fast service deployment and coverage extension capability, S-UMTS—as a direct consequence of its broadcast nature and ubiquitous coverage—offers a natural way

Figure 2: UMTS architecture

to provide multicast and broadcast services in the most cost-efficient manner.

Mobile Station

An MS is defined as a device allowing a user access to network services and the *universal subscriber identity module* (USIM). It is involved in every major UMTS procedure: call setup and management, handoff procedures, and mobility management. The USIM contains the functions and data needed to identify and authenticate users, as well as a copy of the user's service profile and the security parameters needed for confidentiality and integrity services. A mobile station has many different types of identities. Most of these UMTS identity types are taken directly from GSM specifications and include the following.

- The international mobile subscriber identity represents the permanent user identity as stored in the USIM secure component.
- The *temporary mobile subscriber identity* (TMSI) is a temporary identifier in the local network in which a user is registered. It is used to avoid user traceability, which may lead to the compromise of user identity confidentiality. The temporary identities are changed regularly.
- The *packet temporary mobile subscriber identity* (P-TMSI) replaces the TMSI in the packet-switched domain.
- The *mobile subscriber integrated services digital network* (MSISDN) represents the user phone number.
- The *international mobile station equipment identity* (IMEI) represents the mobile equipment serial number and can be used for fraud prevention.
- The *international mobile station equipment identity and software number* (IMEISV) is similar to the IMEI and addresses both hardware and software identity.

UMTS mobile stations can operate using one of the three modes: (1) simultaneous packet and circuit switching, (2) packet switching, or (3) circuit switching.

In the combined *packet-switching* (PS) and *circuit-switching* (CS) mode of operation, the MS is attached to both the PS and CS domains. Therefore, the MS is capable of simultaneously operating PS services and CS services.

In the PS mode of operation, the MS is only attached to the PS domain and may only operate services of the PS domain. However, this does not prevent CS-like services to be offered over the PS domain.

In the CS mode of operation, the MS is only attached to the CS domain and can only operate services of the CS domain.

UMTS Terrestrial Radio Access Network Architecture

The UTRAN consists of a radio network subsystem connected to the core network through the Iu interface (3GPP 2004, "General"). It is responsible for handling the radio functions of the system (3GPP 2002, "UTRAN"). As depicted in Figure 3, the UTRAN consists of node B's and several RNCs, which play roughly equivalent roles to these performed in GSM by the base transceiver stations and base station controller, respectively.

Node B

Node B in UMTS is the physical unit for radio transmission and reception with cells. In fact, its main role is to perform physical layer functions (e.g., modulation and demodulation, coding, interleaving, spreading, etc.). The main tasks of node B are the air-interface transmission and reception and *code division multiple access* (CDMA) physical channel coding. It also measures quality and the strength of the connections and determines the frame error rate. It transmits these data to the RNC as a measurement report for handoff and macrodiversity. In addition, the node B also participates in power control because it enables the MS to adjust its power.

Radio Network Controller

The RNC is one of the key elements of the UTRAN. It connects node B to the transport network. It is responsible for handoff decisions that require signaling to the MS. Node B's resources are controlled by the RNC. Typically, the functions of RNC are:

- radio resource control, admission control, and channel allocation;
- power control settings, handoff control, and macrodiversity;
- encryption;
- segmentation and reassembly;
- broadcast signaling; and
- open-loop power control.

Figure 3: UTRAN architecture

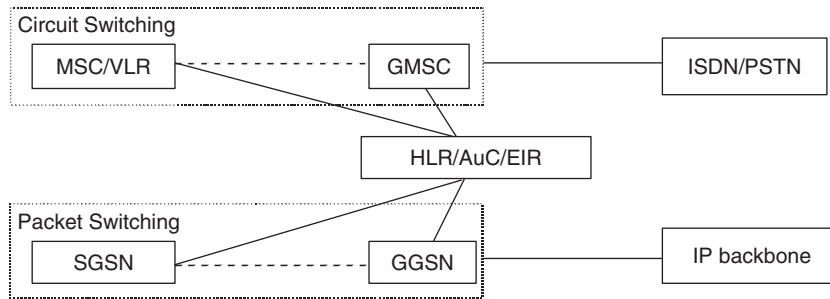

Figure 4: UMTS release 99 core network architecture

Core Network Architecture

The CN is responsible for such major communication functions as call establishment and handling, data transmission, mobility management, and traffic management. In core networks, two layers are defined: (1) the radio network layer and (2) the transport network layer. Figure 4 shows a block diagram of a typical CN that has basically circuit-switched and packet-switched building blocks. The major circuit-switched components are the mobile services switching center, the visitor location register, and the gateway mobile services switching center.

The *mobile services switching center* (MSC) is the interface between the cellular network and external fixed circuit-switched telephone networks such as the PSTN. This component performs the routing of calls from an external network to an individual mobile station and all of the switching and signaling functions for mobile stations located in a geographical area designated as the MSC area. Additional functions include carrying out the procedures required for location registration, handover, and encryption parameter management.

The *visitor location register* (VLR) component is generally implemented in connection with an MSC. It holds information related to every mobile station that roams into the area serviced by the associated MSC. Thus, the VLR contains information about the active subscribers in its network, even from those to whom this network is their home network. As subscribers register with different networks, the information in their *home location registers* (HLRs) is copied to the VLR in every network visited and discarded when the subscribers leave those networks.

The *gateway MSC* (GMSC) plays the role of gateway to external networks.

Packet-switched components are of two types: (1) serving GPRS support node and (2) gateway GPRS support node.

The *serving GPRS support node* (SGSN) component is responsible for mobility management and IP packet session management. It routes user packet traffic from the radio access network to the appropriate *gateway GPRS support node* (GGSN), or the gateway between the cellular network that uses UMTS and external packet data networks such as the Internet and corporate intranets.

The network elements shared by both domains (CS and PS) are the following:

- The *home location register* stores data related to each subscriber of the services provided by the mobile network.

This information is entered when a user subscribes to the network.

- For each subscriber, the *authentication center* (AuC) stores an authentication key (K) as well as the corresponding IMSI, which are permanent data entered at subscription time.
- The *equipment identity register* (EIR) checks to see whether a mobile device is valid.

UMTS Interfaces

Three interfaces are used in UMTS: Iu, Iur, and Iub. The service provided by each is as follows.

- The Iu interface connects UTRAN to the transport network. It is logically divided into two entities: (1) the Iu-CS, through which an RNC is connected to the CN circuit-switched domain; and (2) Iu-PS, through which an RNC is connected to the CN packet-switched domain.
- The Iur is the interface between two RNCs (3GPP undated, TS 25.421). Using this interface, RNCs can communicate during handoff with the serving RNC.
- The Iub interface connects an RNC and a node B and allows an RNC a node B to negotiate the radio resources (for example, they can negotiate adding or deleting cells controlled by node B) to support communication of the dedicated connection between an MS and a serving radio network subsystem (3GPP Services and System Aspects, TS 25.431).

UMTS LAYERS

The radio interface is layered into three protocol layers, as depicted in Figure 5. Each layer plays an important role as described below:

Layer 1 comprises the W-CDMA physical layer.

Layer 2 comprises the *medium access control* (MAC), the *radio link control* (RLC), the *packet data convergence protocol* (PDCP), and the *broadcast and multicast control* (BMC).

Layer 3, the network layer, is divided into the *radio resource control* (RRC), the *mobility management* (MM), and the *connection management* (CM) sublayers.

UMTS Physical Layer

The physical layer defines the access to the transmission media, the physical and electrical properties, and how to

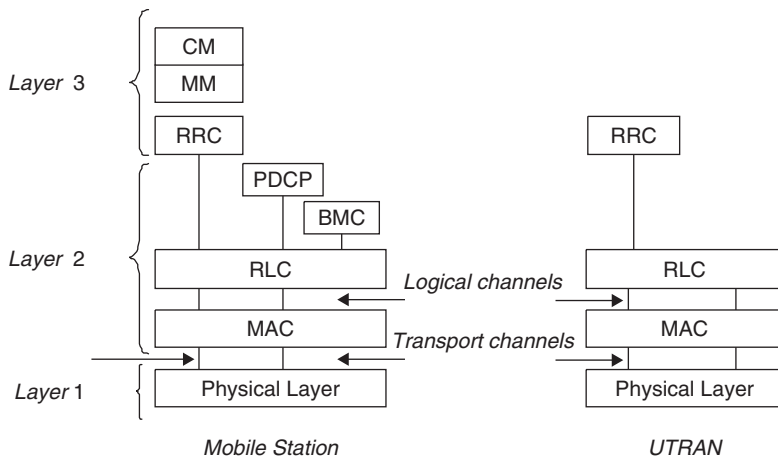

Figure 5: Radio interface protocol architecture

activate and deactivate a connection. It offers data transport services to higher layers. The main functions performed by this layer are multiplexing of transport channels and demultiplexing of coded composite transport channels, error detection, modulation and demodulation, spreading and despreading of physical channels, measurements and indication to higher layers [e.g., frame error rate, *signal-to-interference ratio* (SIR), interference power, transmit power], macrodiversity distribution and combining, soft handover execution, frequency and time synchronization, and power control.

W-CDMA scheme allows mobile and network systems to transmit over a single, widely spread frequency band and different transmitters. The user data sequence is multiplied with a so-called spreading sequence, whose symbol or chip rate is much higher than the user data rate. This spreads the user data signal to a wider frequency band. The relation between user data rate and chip rate is called a *spreading factor*. The chip rate in W-CDMA is 3.84 Mcps, and spreading factors are in the range of 4 to 512; therefore, the user net bit rates supported by one code channel are in the range of 1 to 936 kbps in the downlink. As many as three parallel codes can be used for one user, giving bit rates as high as 2.3 Mbps. In the uplink, data rates are half of these figures because of modulation differences.

The W-CDMA standard includes two modes of operation:

1. The W-CDMA FDD mode is utilized to perform an efficient use of the paired and unpaired band of the allocation spectrum (as depicted by Figure 1).
2. The W-CDMA TDD mode is intended for applications in macrocell and microcell environments with medium data rates and high mobility. The W-CDMA TDD mode is particularly well suited for environments with high traffic density and indoor coverage, where client applications require high data rates.

W-CDMA TDD and W-CDMA FDD differ in the physical layer of UTRA protocol layers because they use different duplex and different multiple access techniques. All other protocols and system components are nearly the same.

The W-CDMA transmission is split into 10-ms radio frames, each of which consists of fifteen time slots of 666 ms (2560 chips). The bit rate and channel coding can be changed in every 10-ms frame, offering highly flexible control of the user data rate. Every time slot has bits reserved for pilot signal, power control, and, if necessary, transmission diversity. *Diversity* is a method to combat noise and fading (Pedersen et al. 1999). It provides the receiver with multiple copies of signals generated by the same underlying data.

UMTS Link Layer

The data-link layer contains four sublayers: (1) the MAC layer; (2) the RLC layer; (3) the PDCP, and (4) the BMC. The PDPC enables the independence of layer 3 and lower layers by making possible their independent development. The main functions of BMC are the scheduling and delivery of cell broadcast and multicast messages.

UMTS MAC Layer

The MAC layer is located on top of the physical layer. It is responsible for mapping logical channels used for communication with the higher layers into physical ones. It is also used for priority handling of users' equipment and the data flows of MS, traffic monitoring, ciphering, and multiplexing processes.

UMTS RLC Layer

The RLC layer is responsible for the acknowledgement and unacknowledgement of data transfer, establishment connections, QoS settings, and ciphering. There is one RLC connection per radio carrier. Management addresses the following tasks:

- Communication management includes functions and procedures that are related to user connections.
- MM includes functions and procedures that are related to mobility and security.
- Radio resource management includes algorithms that are related to the radio resource.

UMTS Network Layer

UMTS RRC Layer

The radio resource control sublayer constitutes the split of layer 3 in the radio interface. It handles the control plane signaling between the mobile station and the UTRAN (3GPP 2005). Some of the functions offered by the RRC include the following:

- broadcasting information provided by the core network;
- management of connections between the mobile station and the UTRAN, including their establishment, reestablishment, maintenance, and release;
- management of the radio bearers, including their establishment, maintenance, release, and corresponding connection mobility;
- RRC connection mobility functions;
- paging and notification;
- control of requested quality of service;
- mobile station measurement reporting and control of the reporting;
- control of the encryption;
- timing advance control;
- configuration of the MAC and RLC; and
- controlling packet data size to be sent on transport channels.

Channel Structure

The MAC can support multiple channel types: The transport channels are depicted between MAC and layer 1, and the logical channels are depicted between MAC and RLC.

Transport Channels

These channels are resources that are divided among all or a group of users in a cell. They include the following different types:

- A *random access channel* is used on the uplink from the MS to the network to request a *dedicated traffic channel* (DCCH).
- A *forward access channel* carries downlink control information to terminals known to be located in the cell under control. It is further used to transmit a small amount of downlink packet data.
- A *downlink shared channel* carries dedicated user data or control information and can be shared in time between several users. It is considered as a pure data channel and is always associated with a downlink dedicated channel.
- A *common packet channel* carries uplink packet-based user data. It supports uplink inner loop power control with the aid of a downlink dedicated physical control channel.
- An *uplink shared channel* is used for *time division duplexing* (TDD) operation only.
- The *broadcast channel* is used to transmit specific information to the UTRAN or to a given cell (e.g., random

access codes, cell access slots, cell type transmit diversity methods, etc.)

- The *paging channel* carries data that are relevant to the paging procedure. The paging message can be transmitted in a single or several cells, according to the system configuration.

Logical Channels

The MAC layer provides data transfer services on logical channels. A set of logical channel types is defined for different kinds of data transfer services as offered by MAC. The control channels used for transfer of control plane information are the broadcast control channel, the paging control channel, the common control channel, the DCCH, and the shared channel control channel.

The traffic channels are used for the transfer of user plane information only using the dedicated traffic channel and the common traffic channel.

MOBILITY MANAGEMENT

MM is the essential technology that enables networks to support mobile users, allowing them to move, while simultaneously offering incoming calls, data packets, and other services. It is concerned with location procedures and handoff management. It enables communication networks to locate roaming terminals in order to deliver data packets and maintain connections.

Location Management

Location management is concerned with the procedures that enable the system to discover the current attachment point (or current location) of the mobile user for call delivery. It contains two processes: *location registration* and *service delivery*.

In location registration, the mobile terminal periodically notifies the network of its new access point, allowing the network to authenticate the user and revise the user's location profile. With service delivery, the network can be queried for the user's location profile; the current position of the mobile host is then found.

The UMTS scheme consists of a two-level hierarchy of location registers (the home location and the visitor location registers) that are used to track mobile registration. Information about each user (such as the types of services subscribed) and location information are stored in a user profile located at the HLR. Each VLR stores the information of the mobile station (downloaded from the HLR) visiting its associated area.

Location Registration

To correctly deliver calls, the system must keep track of each mobile's location. As described previously, the databases HLR and VLR are used to store the location information. As the mobiles move around the network coverage area, this information may no longer be accurate. To ensure that calls can be delivered successfully, the databases are periodically updated through a process called *location registration*. The registration steps are given as follows (see Figure 6).

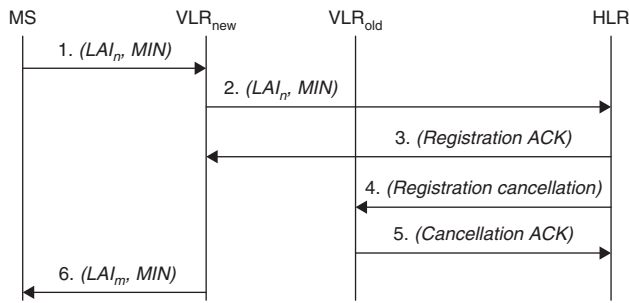

Figure 6: Location registration

- The MS enters a new local area and transmits a location update message containing the *local area identity* and *mobile identification number* (LAI_n , MIN) to the new VLR (VLR_{new}). This is formally denoted by:

$$MS \rightarrow VLR_{new} \quad (LAI_n, MIN)$$

- If the new local area belongs to a different VLR, then the VLR_{new} determines the address of the HLR of the MS from its MIN. Otherwise, location registration is complete:

$$VLR_{new} \rightarrow HLR \quad (LAI_n, MIN)$$

- The HLR performs the required procedures to authenticate the MS and records the ID of the VLR_{new} of the MS. The HLR then sends a registration *acknowledgment* (ACK) message to the VLR_{new} :

$$HLR \rightarrow VLR_{new} \quad (\text{registration ACK})$$

- The HLR sends a registration cancellation message to the VLR_{old} :

$$HLR \rightarrow VLR_{old} \quad (\text{registration cancellation})$$

- The VLR_{old} removes the record of the MS and returns a cancellation acknowledgment message to the HLR:

$$HLR \rightarrow VLR_{old} \quad (\text{cancellation ACK})$$

- The VLR_{new} sends to the MS the new local area identity (LAI_m),

$$VLR_{new} \rightarrow MS \quad (LAI_m, MIN)$$

Service Delivery

The call delivery procedures locate the mobile terminal based on the information available in the HLR and the VLR when a call for a mobile terminal is initiated. Two major steps are involved in call delivery: (1) determining the serving VLR of the called mobile station, and (2) locating the visiting cell of the called mobile terminal. Locating the serving VLR of the MS involves the following database lookup procedure (Figure 7 depicts the steps and messages involved in this process):

- The calling mobile terminal sends a call initiation signal to the serving MSC of the mobile terminal through a nearby base station.
- The MSC determines the address of the HLR of the called mobile terminal by global title translation and sends a location request message to the HLR.
- The HLR determines the serving VLR of the called mobile terminal and sends a route request message to the VLR. The VLR then forwards the message to the MSC serving the mobile terminal.
- The MSC allocates a temporary identifier called the *temporary local directory number* (TLDN) to the mobile terminal and sends a reply to the HLR together with the TLDN.
- The HLR forwards this information to the MSC of the calling mobile terminal.
- The calling MSC requests a call setup to the called MSC through the *signaling system 7* (SS7) network.

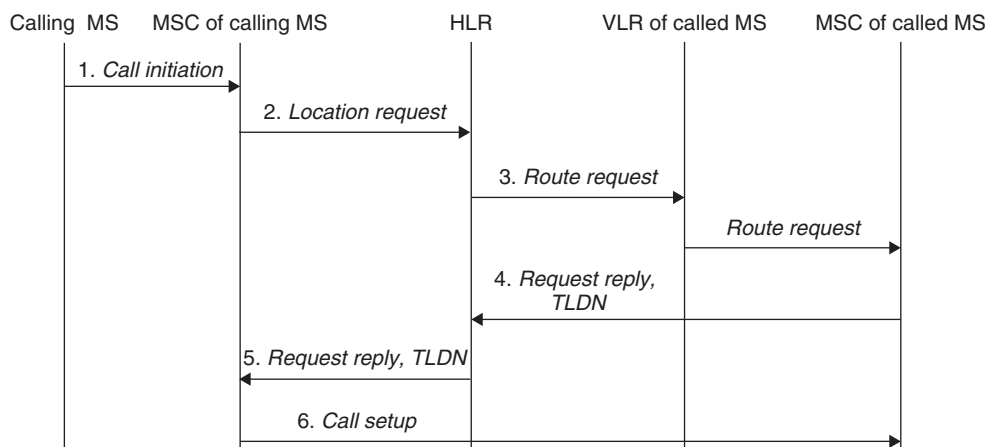

Figure 7: Service delivery

Handoff Management

The ability to make and receive calls anywhere at any time, creating a totally new dimension in human communications, has frequently been advertised as the main advantage of new wireless systems. Handoffs are a key concept in providing this mobility. It enables the user to move within the network while in a call and involves the reconfiguration of the communication channels. Handoff management is the process of initiating and ensuring a seamless and lossless handoff of a mobile station from the region covered by one node to another. It consists of three operations: handoff decision, network connection, and data flow control.

Requirements of Handoff

To achieve a high level of efficiency while providing acceptable guarantees for quality of service, the handoff performed by UMTS should satisfy the following requirements.

- *Latency* is the time required to perform the handoff; it should be appropriate to the rate of mobility of the terminal and the nature of data transferred.
- With *scalability*, the handoff procedure should support handoffs within the same cell and between different base stations in the same or in different networks.
- Minimal drop-off and fast recovery.
- The quality of service should be maintained or renegotiated after the handoff process if needed.
- Minimal additional signaling, or the reduction of control signals, has been the fundamental design consideration. In fact, handoff signaling should have a minimal impact on networking performance and quality.

Handoff Decision

The handoff decision needs the monitoring of the current network connections, recognizing the need for handoff and subsequently initiating it. In most technologies, the conventional criteria used to reflect the state of the current network connection are the received signal strength, SIR, coverage area, *bit error rate* (BER), and *block error rate* (BLER). In addition to these criteria, UMTS takes into consideration other factors such as the status of neighboring base stations and different radio link measurements. Two basic criteria for measurements reporting are used: *periodic reporting* and *event-triggered reporting*. The different types of air-interface measurements, performed at every cell, are classified into the following six categories.

- **Intrafrequency measurements:** These are measurements on downlink physical channels made at the frequency used by the active set.
- **Interfrequency measurements:** These are measurements on downlink physical channels at frequencies that differ from the frequency used by the active set.
- **Inter-RAT (i.e., *radio access technology*) measurements:** These are measurements on downlink physical channels belonging to another radio access technology than UTRA network such as GSM.

- **Traffic volume measurements:** These measurements control the uplink traffic volume.
- **Quality measurements:** These measurements report on downlink quality parameters such as the downlink transport block error rate. A measurement object corresponds to one transport channel in case of BLER. Performed on a time slot, in case of SIR, it is used with the TDD mode only.
- **MS-internal measurements:** These measurements report on MS transmission power and MS received signal level.
- **MS positioning measurements:** These measurements track the MS position.

Handoff Types

UMTS provides mobile users four types of handoff: softer, soft, hard, and intertechnology.

Softer Handoff. A *softer handoff* is also called an *inter-sector handoff*. It occurs when the mobile station is in the overlapping coverage area of two adjacent sectors belonging to the same node B serving one cell as shown by Figure 8, where the MS is connected to two adjacent sectors (1 and 2). One important advantage of softer handoff is the shorter service interruption caused by handoff. A disadvantage is, however, observed with a softer handoff: data duplication during the softer handoff phase may degrade the total system throughput.

Soft Handoff. *Soft handoff* means that the radio links are added and removed in a way that the MS always keeps at least one radio link to the UTRA network. A soft handoff occurs when the mobile station is in the overlapping coverage area of two or more adjacent cells (as shown in Figure 9). The user has two or more simultaneous connections to the UTRA network as part of the network using different air-interface channels concurrently. Normally, soft handoff can be used when cells that operate on the same frequency are changed.

A key benefit of soft handoff is the path diversity on the forward and reverse traffic channels. Diversity gain is obtained because less power is required on the forward and reverse links. This gain implies that the total system interference is reduced. As a result, the average system capacity is improved.

Figure 8: Softer handoff

Figure 9: Soft handoff

Hard Handoff. *Hard handoff* is different from the soft handoff process. It means that a connection is broken before a new radio connection is established between the user equipment and the radio access network. Hard handoff can be seamless or nonseamless. *Seamless* hard handoff means that the handoff is not perceptible to the user. In practice, a handoff that requires a change of carrier frequency (i.e., interfrequency handoff) is always performed as a hard handoff.

The main problem observed with hard handoffs is characterized by the blocking probability experienced by users entering a new cell. This probability can be reduced by giving priority to handoff users over new users. This can be done, for example, by reserving a certain part of the capacity in each cell for users with ongoing communication.

Intertechnology Handoff. From the technical point of view, one can distinguish between intrasystem and intersystem handoffs. For UMTS, the following types of *intersystem* handoff are specified:

- In an intersystem *FDD* or *TDD* handoff, the calls are transferred from FDD access mode to TDD.
- In an intersystem *TDD* or *FDD* handoff, the calls are transferred from TDD access mode to FDD.
- In an intersystem *UMTS-2G* handoff, a call is transferred from one UMTS cell to a 2G cell (e.g., handoff from UMTS to GSM).
- In an intersystem *2G-UMTS* handoff, a call is transferred from one 2G cell to a UMTS cell (e.g., handoff from GSM to UMTS).

Intersystem handoff is a necessary feature to support the upgrade of 2G systems to UMTS as well as support the different UMTS modes. Obviously, the mobile station has to support both modes. Even though the intersystem handoff is performed after a network evaluation of resources, the mobile terminal must also support the necessary measurements to achieve it.

UMTS QUALITY OF SERVICE

Typically, QoS refers to the collective effect of service performance that determines the degree of satisfaction that end users feel about the service they are getting (3GPP

2004, “QoS”). A major goal of 3G networks is to deliver multimedia services that meet sophisticated end-to-end QoS requirements. The difficulty in providing this in 3G wireless systems results from the mobility of nodes and the unpredictable nature of the radio link. In particular, the access network is one of the most critical parts of the system because both the air interface and the terrestrial transmission resources it involves are extremely limited and the QoS constraints are tight. Hence, a 3G mobile communication network operator has to maximize the number of users while maintaining user QoS requirements. In this respect, two aspects can be clearly differentiated: (1) the network planning, which is the design of the fixed network infrastructure in terms of number of cell sites, cell site location, and number and architecture of concentration nodes; and (2) the radio resource allocation.

Multimedia traffic puts heavy bandwidth demand on cellular networks. Typically, bandwidth is the most critical resource needed by multimedia services in cellular networks. It requires that ad hoc mechanisms efficiently assign the available resources. Therefore, the need arises for sophisticated radio resources management mechanisms, which are responsible for the utilization of air-interface resources. Also, the implementation of efficient algorithms is needed to guarantee QoS requirements and provide high capacity.

UMTS Services

Because of the limitations of the air-interface capacity, the QoS classes supported in UMTS are different from those supported by fixed networks. Two types of services can be defined for 3G mobiles: *real-time services* (e.g., videoconferencing) and *non-real-time services* (e.g., database applications). In this context, the 3GPP, which is the body responsible for UMTS specifications, defined four distinct traffic classes for UMTS (3GPP 2004, “QoS”): conversational, streaming, interactive, and background.

1. The *conversational class* is intended to carry extremely delay-sensitive applications. The best-known application of this class is the voice service.
2. Within the *streaming class*, a client browser can start displaying streaming data before an entire file has been transmitted. Streaming is a one-way transport mechanism and requires the delay variation of the end-to-end flow to be limited.
3. The most important characteristic of the *interactive class* is that the content of packets be preserved and transparently transferred with low BER. The known applications for this class are Web browsing and network games.
4. The *background class* contains services that are most delay nonsensitive traffic. The known applications of this class are services that allow file downloading (e.g., FTP), e-mail, and SMS.

Resources Management

Another significant feature introduced by UMTS is the provision of QoS on an end-to-end basis. The UMTS QoS idea is based on the goal of efficient use of resources in

a packet-switched network (Heier and Malkowski 2002). The main factors that affect the QoS as perceived by the user are the *new call blocking probability* and the *hand-off blocking probability*. The lack of network resources can cause unsuccessful calls. The blocking probability can occur at the radio link, at the interworking unit between the mobile and the fixed networks, or at the transmitting network. To reduce the blocking probability values, it is necessary to improve resource allocation and reserve resources for handoffs (3GPP 2004, "Radio").

Call Admission

Within the CDMA technique, all users share the bandwidth and each new connection increases the interference level of the other connections, affecting their quality of service. To keep the interference below a tolerable level, the number of users is limited to a certain threshold. The *call admission control* has to avoid overload situations when admitting or denying new users (Corbett and Everit 2003). Admission control principles make use of the load factors and an estimation of the load increase that the establishment of a new call would cause on the radio network.

Congestion Control

Congestion occurs when the admitted users cannot be satisfied with the normal services agreed for a given percentage of time because of an overload occurrence (Kasera et al. 2005). The congestion state then has to invoke some procedure—a *congestion control*—that could prevent some users from getting the normal quality-of-service margin beyond the contracted percentage of time.

Power Control

Power control mechanisms are used to reduce mobile's transmission power. In WCDMA, this is a closed-loop power command, which is a combination of outer and inner closed-loop control. The inner closed-loop power control adjusts the transmitted power in order to keep the received SIR equal to a given target. This SIR target is fixed according to the received BLER or BER. The setting of the SIR target is done by the outer loop power control, which is part the RRC layer, in order to match the required BLER (3GPP 2001, "Physical layer").

The UMTS system has three main schemes of power control (3GPP undated, "Power control"). In the first scheme, the transmitted power is updated at each time slot. It is increased or decreased by a fixed value (ΔdB):

- If $\text{SIR}_{\text{estimated}}$ is greater than $\text{SIR}_{\text{target}}$, then the transmitted power control command to transmit is 0, meaning that a transmit power decrease is requested; and
- if $\text{SIR}_{\text{estimated}}$ is less than $\text{SIR}_{\text{target}}$, then the transmitted power control command to transmit is 1, or a transmit power increase is requested.

The second scheme consists of performing a hard decision based on values read from five time slots. If all of the time slots yield a command to increase or decrease power, then it will be done for the next five time slots. If

any of the commands in a group of five time slots differs from the other commands in the same group, then the power shall remain at the same level for the next five time slots.

The third scheme consists of a soft decision based on the measurements in three time slots, yielding an increase or decrease in power according to the overall weighed decision of the three time slots.

Both uplink and downlink have two different types of power control. For uplink, schemes 1 and 2 are used. The ΔdB for type 1 is either 1 dB or 2 dB, whereas the ΔdB used for type 2 is 1 dB. For downlink, schemes 1 and 3 are used. The ΔdB in downlink can be 0.5 dB, 1 dB, 1.5 dB, or 2 dB; it is mandatory that the UTRAN support at least the value of 1 dB.

Resource Allocation

Because of increasing traffic asymmetry in mobile communications, there is a significant need to improve resource allocation in UMTS. Two methods of allocation are available on medium access control: *fixed channel allocation* (FCA) and *dynamic channel allocation* (DCA) (Wie and Cho 2001; Corbett and Everit 2003).

Fixed Channel Allocation. With the FCA method, the numbers of uplink and downlink channels are statically defined. There are two scenarios to implement FCA: (1) symmetric fixed channel allocation and (2) asymmetric fixed channel allocation. The symmetric case uses only one more slot for the downlink than the uplink. The asymmetric case uses more slots for the downlink than the uplink.

Dynamic Channel Allocation. DCA enables a cellular system to adapt flexibly to different load situations, thereby increasing bandwidth utilization and decreasing new call blocking. The numbers of uplink and downlink channels were dynamically defined. DCA provides an efficient allocation of the available resources by shifting the switching point within a transmission frame to accommodate the varying traffic in each direction. Thus, DCA is a better access method than FCA in a TDD-CDMA system.

Resources Reservation

In cellular networks, each mobile maintains connectivity via an *active set* (this is defined as the set of nodes B that the MS is simultaneously connected to) of cells, which are involved with the mobile during handoff. To support applications and protocols used on wired networks, the handoff processing must not significantly affect the end-to-end loss or delay of any communication. Handoff requests compete with new call requests to gain admission into a target cell. The call admission control protocol should give prioritized admission to handoff requests because, from the user's point of view, disruptions during handoffs are considered more objectionable than new call blocking.

In Bartolini (2001), a nonpreemptive prioritization scheme for call admission control in cellular networks was presented and analyzed. Two kinds of users can compete for the access to the limited number of frequency

channels that are available on each cell: High-priority users represent handoff requests, whereas low-priority users correspond to initial access requests originated within the same cell. Queuing of handoff requests can be also considered.

UMTS SECURITY

The GSM lacked mutual authentication and did not provide any protection in the core network of the cellular system. The integration of security mechanisms in UMTS makes use of the experiences, which were made especially in connection with the GSM and GPRS and their weaknesses (European Telecommunications Standards Institute 2000). In fact, the UMTS security is based on second-generation security procedures with different enhancements and extensions. UMTS comprises a complete security infrastructure that contains two levels: access control and network security (3GPP 2001, “3G security”; 3GPP 2002, “3G security”).

Access Control

The access control deals with security issues concerning the air interface and the UTRA network. Network access security features can be further classified into the categories of mutual authentication, confidentiality, and data integrity.

Authentication and Key Agreement

In GSM systems, the network requires an authentication of mobile users, but the network does not have to authenticate itself to the user. Therefore, eavesdropping techniques such as the use of so-called IMSI catcher devices may identify a single user and deactivate the encryption functionality. UMTS introduces a new protocol for *authentication and key agreement* (AKA), which should solve these problems and be secure against man-in-the-middle attacks (3GPP 2002, “Third Generation”). The AKA is the combination of terminal authentication and session key exchange. Its goal has twofold actions: (1) The user and the network authenticate each other and (2) the user and network agree on *cypher* (or *encryption*) and *integrity keys* (CK and IK, respectively).

The mechanism AKA is based on a challenge-response authentication protocol conceived in such a way as to achieve maximum compatibility with GSM's subscriber authentication and key establishment protocol; this makes the transition from GSM to UMTS easier. A challenge-response protocol is a security measure that is intended for an entity to verify the identity of another entity without revealing a secret password shared by the two entities. The key concept with this scheme is related to the fact that each entity must prove to the other that it knows the appropriate password without actually revealing or transmitting it.

The UMTS AKA process is invoked by a serving network after (1) first registration of a user, (2) a service request, (3) a location update request, (4) an attached

request, or (5) a disconnect request or a connection reestablishment request.

To clarify the description of the generation of authentication vectors, the following symbols and notations are used:

- K for the authentication secret key;
- f_1, f_1^*, f_2 for the authentication functions defined by the UMTS standard (the functions with $*$ are used in the resynchronization event);
- f_3, f_4, f_5 for the key generation functions;
- SQN for sequence number; and
- \parallel, \oplus for concatenation and exclusive OR.

Generation of Authentication Vectors at AuC

Upon receipt of an authentication data request, the AuC starts generating a fresh sequence number SQN and an unpredictable challenge RAND. Then it sends the authentication vector to the VLR. The authentication vector contains a RAND, a network *authentication token* (AUTN), an *expected result* (XRES), a temporary IK, and a temporary CK, where:

- $MAC = f_{1K}(SQN \parallel RAND \parallel AMF)$ is the message authentication code;
- $XRES = f_{2K}(RAND)$ is the expected response;
- $CK = f_{3K}(RAND)$ is the cipher key;
- $IK = f_{4K}(RAND)$ is the integrity key; and
- $AK = f_{5K}(RAND)$ is the anonymity key.

Figure 10 depicts the generation actions used to create an authentication vector AV by the AuC.

The *authentication management field* (AMF) is used to define operator-specific options in the authentication process—for example, the use of multiple authentication algorithms or limits on key lifetime.

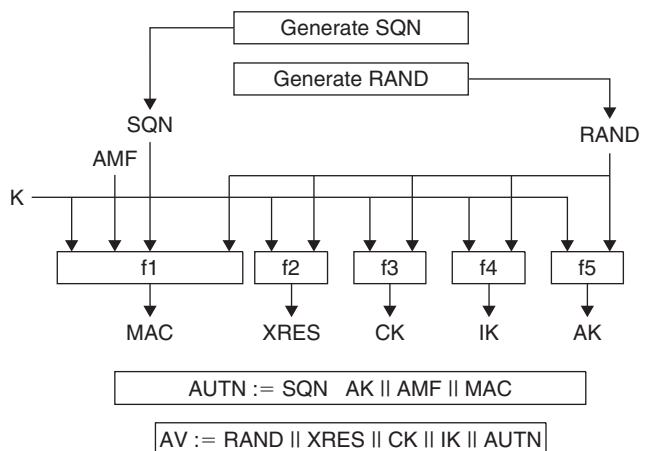

Figure 10: Generation of authentication vectors at AuC

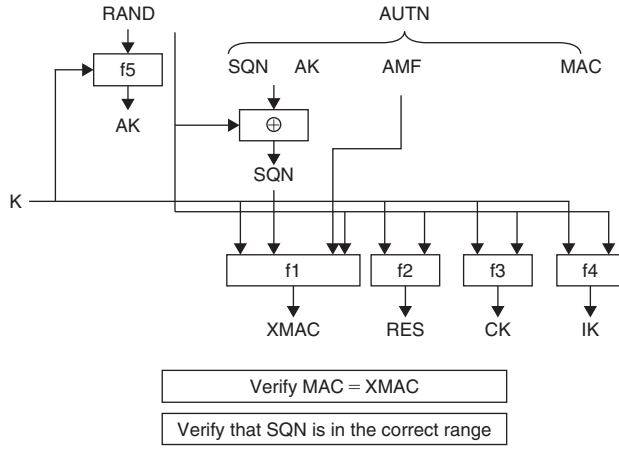

Figure 11: Generation of authentication vectors at USIM

Generation of Authentication Vectors at USIM

The universal subscriber identity module first computes the *anonymity key* [$AK = f5_K(RAND)$] and retrieves the sequence number $SQN = (SQN \oplus AK) \oplus AK$. Next the USIM computes $XMAC = f1_K(SQN \parallel RAND \parallel AMF)$ and compares this with MAC, which is included in AUTN. If they are different, the user sends a user authentication reject back to the VLR or SGSN with an indication of the cause, and the user abandons the procedure. If the MAC verification was successful, the USIM verifies that the received sequence number SQN is in the correct range. If the sequence number is considered to be in the correct range, the USIM then computes $RES = f2_K(RAND)$; otherwise, it sends a synchronization failure message back to the VLR or SGSN, including information about an acceptable sequence number, and abandons the procedure. Figure 11 summarizes the authentication-vector generation at the USIM.

Authentication Procedures

UMTS provides a set of procedures for authentication. These procedures work as follows.

- The mobile station discovers a VLR or SGSN. It sends its current temporary identity TMSI to the network. If the network cannot resolve the TMSI, then it requests the mobile station to send its permanent identity; the mobile station answers the request with the IMSI:

$MS \rightarrow VLR \text{ or } SGSN \quad (TMSI \text{ or } IMSI)$

- Once it has identified the MS, the VLR or SGSN requests authentication data from the home network of the mobile station:

$VLR \text{ or } SGSN \rightarrow AuC \quad (IMSI)$

- Upon receipt of a request from the VLR or SGSN, the AuC sends an ordered array of n authentication vectors to the VLR or SGSN. Each authentication vector

contains a random challenge RAND, the corresponding AUTN, an XRES, an IK, and the CK:

$AuC \rightarrow VLR \text{ or } SGSN \quad (RAND, AUTN, XRES, IK, CK)$

- Once it has received the authentication vector, the VLR or SGSN selects the one authentication vector from the ordered array ($i \in [1, n]$) and sends the parameters $RAND_i$ and $AUTN_i$ to the mobile station:

$VLR \text{ or } SGSN \rightarrow MS \quad (RAND_i, AUTN_i)$

- The mobile station verifies $AUTN_i$ and computes the response (RES_i) to the challenge, the cipher key (CK_i), the integrity key (IK_i), and the authentication key (AK_i). If $AUTN_i$ is not correct, then the mobile station discards the message. Then the mobile station sends its authentication response (RES_i) to the visited network.

$MS \rightarrow VLR \text{ or } SGSN \quad (RES_i)$

- The VLR or SGSN checks whether $RES_i = XRES_i$ and decides which security algorithms the radio subsystem is allowed to use.
- The VLR or SGSN sends the allowed algorithms to the radio subsystem.
- The radio access network decides which (of the allowed) algorithms to use.
- The radio access network informs the mobile station of its choice in the security mode command message. The message also includes the security capabilities the network received from the mobile station in step 1. This message is integrity protected with the integrity key IK_i .
- The MS validates the integrity protection and checks the correctness of the security capabilities.

Finally, let us note that for compatibility with the GSM security architecture, the handoff between UMTS and GSM will be needed frequently. The UMTS AKA has been designed in such a way that roaming and handoff between GSM and UMTS works as smoothly as possible as far as security is concerned. This is facilitated by the similarity between UMTS quintets and GSM triplets. Conversion functions are specified to convert quintets into triplets and vice versa.

Provision Temporary Identities

UMTS provides user identity confidentiality through the use of temporary identities. After initial registration, users are not identified via their permanent identity IMSIs but instead use TMSIs. To avoid user traceability, which may lead to compromises of user identity confidentiality, temporary identities are changed regularly. The steps of TMSI allocation are as follows:

$VLR \rightarrow MS \quad (IMSI \text{ request})$
 $MS \rightarrow VLR \quad (IMSI)$
 $VLR \rightarrow MS \quad (TMSI \text{ allocation})$
 $MS \rightarrow VLR \quad (TMSI \text{ acknowledgement})$

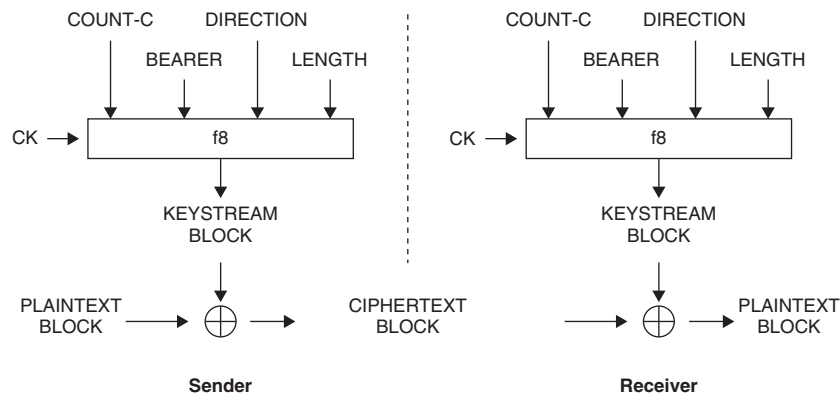

Figure 12: UTRAN encryption

UTRAN Encryption

Figure 12 shows the encryption process. It is meant to occur only between the MS and RNC. The encryption algorithm is a proprietary stream cipher called f8, which is a special mode of operation built around the KASUMI block cipher. The UTRA network encryption is based on the CK transported from the AuC to the VLR or SGSN and computed in the USIM. The keys are never transported in the clear over the radio interface. This enables interconnection of RNCs with CN nodes. The confidentiality of both user and signaling data are protected.

In addition to CK, encryption process takes a few more inputs. These are:

- the LENGTH parameter, which specifies how long the keystream shall be, with a maximum allowed length for the keystream of 20,000 bits;
- the DIRECTION and BEARER identities, which are taken into account to avoid reusing the same keystream for both directions or on different radio bearers; and
- the COUNTER, which in turn ensures that the same keystream is never used twice on the same bearer for a single direction.

The confidentiality feature is the same as in GSM, but the entities between which protection is afforded are different. In UMTS, the protection extends to the radio network controller so that microwave links between the base stations and the RNC are also covered.

Figure 13: Integrity check

Integrity Protection

The integrity protection is limited to happen only between the MS and the RNC, as depicted in Figure 13. The integrity key is derived during the AKA procedure. The UMTS integrity algorithm is implemented in the MS and in the RNC. Integrity protection is applied on a per-message basis at the RRC layer. The 128-bit IK is generated during the AKA procedure and is never transported over the radio interface. Several integrity algorithms can be supported, and a four-bit algorithm identifier is defined to indicate which algorithms are supported. This security feature has no equivalent in GSM.

Network Security

The network security comprises security features in the core network. It covers security of the communications between network elements. In particular, the mobile station is not affected by network domain security. Many different security mechanisms have been standardized by the Internet Engineering Task Force for IP-based networks.

Signaling System

A major part of the 3GPP release 99 specifications was devoted to the introduction of a completely new radio access technology while the core network part was an extension of the existing GSM specification set. This is the main reason why the protection mechanisms for core

network signaling were not introduced in release 99. The security has been based on the fact that the SS7 network has been accessible only to a relatively small number of well-established organizations and institutions. It has been extremely difficult for attackers to insert or manipulate SS7 messages.

MAPsec

Starting from release 4, the situation is changing because the number of different operators and service providers that need to communicate with each other is increasing and there is a trend to replace SS7 networks with IP networks.

MAPsec's purpose is to protect confidentiality and integrity of *mobile application part* (MAP) operations (Kaarinen et al. 2001). The security services provided by MAPsec are data integrity, data origin authentication, antireplay protection, and confidentiality (optional).

MAPsec protection operates in three different modes. In the first mode, no security is guaranteed. In the second mode, only integrity is protected. In the third, both confidentiality and integrity are provided.

- For confidentiality, the header of the MAC operation is encrypted. A security header is added to indicate how decryption should be done.
- For integrity, again a MAC is calculated over the payload of the original MAP operation and the security header. A time-variant parameter is also used to prevent replay attacks (Kaarinen et al. 2001).

The MAPsec security model has a few important limitations. It was perceived by some experts to be too expensive to protect all MAP messages, and therefore a scheme to specify subsets of the MAP messages to be protected had to be invented. The protection profile scheme was developed to achieve this while also constraining the interdomain negotiations in order to reduce complexity.

IPsec

The most significant feature that is used for the protection of network domain traffic is the IPsec protocol (Kaarinen et al. 2001). It provides confidentiality and integrity of communication in the IP layer. Communicating parties can also authenticate each other using IPsec (Kaarinen et al. 2001). The main parts of IPsec are the *authentication header* (AH), the *encapsulation security payload* (ESP), and the *Internet key exchange* (IKE) (Internet Engineering Task Force 1998). The AH only provides integrity and message authentication, whereas ESP can provide both integrity and message authentication and confidentiality. In 3GPP release 5, the IKE is based on pre-shared secrets.

One serious problem with IPsec is that the protocol does not support network address translation, a technology that is used to increase the public address space. Also, the use of IPsec together with mobile IP will lead to substantial performance degradation related to extensive protocol overhead. Another serious shortcoming of IPsec is its lack of session resume functionality. In fact, without session resume, the user will have to log on every time a connection is lost, including user authentication and key exchange.

FUTURE WIRELESS NETWORKS

UMTS is a third-generation solution that promises faster communications services—including voice, fax, and Internet—anytime and anywhere with seamless global roaming. Future wireless networks will be built by a combination of many access networks that bring together mobility not only without geographical constraints but also without being tied to one particular backbone network. They will be able to provide a wide variety of new services, mobile multimedia, and global mobility support. In fact, users who have been receiving services in an urban area with access to the Internet will still be able to access services from different geographical sites. Each access network of future wireless networks will have its attributes, requirements, and mechanisms (signal quality, data rate, handoff decision, coverage discovery, security services, authentication models, etc.). This will require more research and development of architectures and protocols to interconnect those heterogeneous networks in a seamless fashion. In this context, many technical challenges need to be faced such as those associated with heterogeneous architectures, seamless handoff, and secure heterogeneous mobility.

Typically, future research must mainly focus on the following.

- Definition of future wireless network architecture that is flexible and open to existing standards: The integration of WLAN increases the capacity and extends the coverage.
- Definition of a scheme for global mobility: Future wireless networks will implement terminal mobility, personal mobility, and service provider portability.
- Development of new methods to guarantee the service continuity in roaming between different access networks.
- Provide a high level of security: Future wireless networks should maintain the same level of security services for mobile users when they roam across different access networks.
- Deployment with software defined radios: Allowing the equipment to be upgraded to new protocols and services, and supporting roaming across diverse network technologies via software upgrades.

Future wireless networks will generally be characterized by multiple radio access technologies, where different access technologies such as cellular networks (GSM, GPRS, UMTS, etc.), satellite-based networks, wireless local area networks, and wired networks should be combined on a common platform to complement each other. This platform may be called *open wireless architecture* (Zarai and Boudriga 2005), and it should address vertical handoff, translation QoS requirements, and resource allocation.

To achieve global mobility, future wireless networks should provide IP mobility. The mobile users are connecting to the unified wireless network and are free to move around the network coverage area. Global mobility should implement the following:

- *terminal mobility*, or the ability of the network to route calls and services to the terminal regardless of its point

of attachment to the network and the access technology it implements;

- *personal mobility*, or the ability of user to access their personal services independent of their terminal attachment points (providing privacy, integrity, and confidentiality may be required with personal mobility); and
- *service provider portability*, which allows users or terminals to move beyond regional mobile networks and be connected to the same service regardless of the service provided, an issue that may need the implementation of such mechanisms as renegotiation and rerouting.

Within a future wireless networks framework, a mobile terminal may transition from a wired network to a cellular network, from a WLAN to a cellular network, or from a cellular network to a satellite connection. Such movement induces packet loss and latency, which can severely damage the quality of data communications. Thus, appropriate handoff mechanisms must be implemented to minimize these parameters and maintain good levels of network performances while attempting to prevent disruption. Issues involved with this objective include:

- predicting, reducing, and estimating low latency;
- reducing signaling messages overhead and processing time; and
- estimating near-zero handoff and call blocking probabilities.

Finally, it is worth mentioning that providing access for every type of network under various mobile environments and the resulting complexity of the future wireless networks systems leave mobility related procedures highly vulnerable. In addition, because location information about mobile users will be extensively used, the providers of services with unlimited access to information must analyze their security procedures to maintain overall privacy and confidentiality. Technical strategies must be developed to achieve reliable authentication and provide significant untraceability for roaming subscribers (even against attacks internal to service providers).

CONCLUSION

This chapter has presented an overview of the development of mobile systems and UMTS. Researchers have considered other types of technologies that could be utilized to extend 3G UMTS network services in dense areas. A WLAN network provides high-speed data communication in restricted coverage areas at a relatively low cost. It allows users to move around in a confined area while still connected to the network. The distinctive advantages of the UMTS and WLAN networks can be combined to provide seamless connectivity when a user moves across heterogeneous access networks.

GLOSSARY

Authentication: Establishing the validity of a claimed identity.

Cell: The smallest geographic area defined for mobile communications systems.

Code Division Multiple Access (CDMA): CDMA is a digital cellular technology that uses spread spectrum techniques that, instead of separating users by frequency, separates them through the use of digital frequency codes across the full available spectrum.

Confidentiality: The assurance that information is not disclosed to inappropriate entities or processes.

Encryption: The cryptographic transformation of data called *plaintext* into a form called *cipher text* that conceals the data's original meaning to prevent them from being known or used.

Fourth Generation (4G): A future wireless network that will enable users to dynamically switch between various wireless access technologies to the IP-based core network.

General Packet Radio Service (GPRS): GPRS is considered a 2.5G wireless technology. It enables high-speed wireless Internet and other communications such as e-mail, games, and applications.

Global System for Mobile (GSM) Communications: GSM is a digital cellular system based on TDMA narrowband technology, which gives users access to time slots on the same frequency bands. It represents a major popular 2G system.

Handoff: A process by which a mobile station changes its point of attachment from one cell to another without interruption in service or loss in connectivity.

Handoff Management: A process of initiating, executing, and controlling handoff of a mobile to ensure the best possible connectivity.

Integrity: The prevention of the unauthorized modification of information.

Location Management: Concerned with the procedures that enable the system to discover the current attachment point (or current location) of the mobile user for call delivery.

Mobility Management (MM): The essential technology that enables networks to support mobile users, allowing them to move, while simultaneously offering them incoming calls, data packets, and other services. It is concerned with location procedures and handoff management.

Quality of Service (QoS): A measure of network performance that reflects the network's transmission quality and service availability.

Roaming: The movement of a mobile station from one wireless network location to another without interruption in service or loss in connectivity.

Seamless Handoff: A handoff that is not perceptible to the user—that is, a smooth transition so that the user does not perceive any delay or interruption of service.

Second Generation (2G): Digital wireless systems that replace analog wireless systems.

Third Generation (3G): Digital wireless systems that will offer wireless Internet services on a worldwide scale, extending the scope of 2G wireless networks from simple voice telephony to complex data applications including voice over IP, video conferencing over IP, Web browsing, and multimedia services. The most prevalent 3G system is UMTS, which is based on W-CDMA.

Time Division Multiple Access (TDMA): Divides a radio frequency available to a network into time slots

and then allocates slots to multiple calls. It is used in digital cellular telephone communication.

Two and a Half Generation (2.5G): A standard that appeared to enhance the 2G wireless networks with best-effort packet-switched data services.

Universal Mobile Telecommunications System (UMTS): UMTS is approved by the International Telecommunications Union and is intended for advanced wireless communications. It represents a major 3G system.

Wideband Code Division Multiple Access (W-CDMA): A 3G wireless technology derived from CDMA that transmits digitized data over a wide range of frequencies to boost speed. It uses wide 5-MHz channels and is associated with UMTS and GSM, where it boosts speed by substituting TDMA technology with CDMA.

Wireless Local Area Networks (WLANs): WLANs use radio waves instead of a cable to connect a user device, such as a laptop computer to a local area network (LAN). They provide Ethernet connections over the air and operate under the 802.11 family of specifications developed by the IEEE.

INTRODUCTION

The International Mobile Telecommunications-2000 (IMT-2000) provides the outline for worldwide wireless access by internetworking the diverse systems of terrestrial and/or satellite-based networks. In fact, this International Telecommunications Union (ITU) initiative has led to a set of recommendations in various areas of new services. Those areas include: band allocation, user bandwidth, flexibility, and richness of classes of service. Although those recommendations aggregated into a set of requirements, the IMT-2000 did not tackle technical specifications on how to achieve those requirements (Collins and Smith 2001). In this chapter, the IMT-2000 requirements, as well as specifications and radio interface technologies proposed by standards forums to meet these requirements, will be discussed. Introductory material for third-generation (3G) systems will be formulated, with special emphasis on wideband code division multiple access (W-CDMA) and code division multiple access 2000 (cdma2000) being the most widely accepted air interfaces in the major parts of the world.

The organization of the chapter is as follows. The first section describes the key specifications and objectives of 3G as well as the motivation behind it. The second section starts with a brief description of the major worldwide standardization bodies and their harmonization efforts. A basic description of the targeted 3G systems is also discussed in this section, both in Europe and North America. Evolution from second-generation (2G)-based systems to 3G is the topic of the third section, which starts with an overview of the cellular concept. The differences

between the three systems—first generation (1G) through 3G—are then presented. The major wireless systems are described, as well as the strategies and evolution paths between the various systems. In the fourth section, the universal mobile telecommunications system (UMTS) is detailed, with descriptions of the different releases. Various aspects are tackled, including architecture, layering, channels, spreading, coding, and modulation. The main focuses of the fifth section are structure and layering, forward and reverse links, and channel coding of cdma2000. Finally, a conclusion summarizes the chapter, and a glossary containing the main wireless communication terms is included to help clarify the associated concepts.

OVERVIEW OF IMT-2000 AND 3G SYSTEMS

3G Systems Evolved from IMT-2000

IMT-2000 was developed to smooth the progress of standards that lay the way for a wireless infrastructure encompassing terrestrial and satellite systems that consider both fixed and mobile access for public and private networks. IMT-2000 is a radio and network access specification that defines the technology and methodology of achieving the following goals:

- Global standards
- Compatibility of service within IMT-2000 and with the fixed networks

- High quality
- Small terminals for worldwide use
- Worldwide roaming capability
- Capability for multimedia applications and a wide range of services and terminals
- Improved spectrum efficiency
- Flexibility for evolution to the next generation of wireless systems
- High-speed packet-switched data-rates:
 - Fixed: 2 Mbps
 - Pedestrian speed: 384 kbps
 - Vehicular speed: 144 kbps

ITU originally aimed to unify and standardize 3G technologies on a worldwide scope. Unfortunately, no consensus was reached because the IMT-2000 left the technical specifications behind its requirements open for proposals from interested organizations. Each organization submitted its proposals, and, in 1999, ITU approved five technologies for terrestrial air interfaces (Collins and Smith 2001). The 3G air interface to be implemented depends on the previously deployed mobile system infrastructure (i.e., the 2G network). Accordingly, the air interface to be used will depend on where in the world 3G is to be deployed. The three main 3G air interfaces are based on code division multiple access (CDMA) technologies: cdma2000, UMTS, and universal wireless communication-136 (UWC-136).

Needs for 3G Systems

Why 3G Systems

Imagine the following scenarios, taken from a technical specifications document of the 3rd-Generation Partnership Project (3GPP; 2005), which 3G technologies made possible. (Please refer to the original document for the complete list of scenarios.) Although this list is neither complete nor exhaustive, it helps to explain the motivation to port to 3G technologies.

- Increasing user expectations of:
 - Accessibility anytime and anywhere
 - Faster multimedia and data access
- Phenomenal growth in:
 - Mobile communications
 - Internet/intranet access
 - Use of laptops, palm tops, and personal digital assistants (PDAs)
 - Electronic commerce
- Future capabilities of 3G wireless:
 - Life in the twenty-first century
 - The need for outstanding applications
 - The need for mobile multimedia services
 - Economy growth
 - The need for high data rates services
 - Open and near global standards

Enhanced User Convenience

1. The user is in a voice communication and receives an incoming IP video communication. The user decides not to accept the communication but diverts the incoming video to a messaging system. The user is given an indication that there is a video message in his mailbox.
2. The user is in a voice communication and receives an incoming video communication. The user decides to accept the communication but wishes to switch between the two communications.
3. The user is idle in a network and not involved in a communication. The user modifies his user profile to divert all voice communications other than those from high-priority, pre-identified callers (e.g., his boss). In this scenario, all e-mails and text messages continue to be received regardless of the sender.
4. On receiving a communication, the calling party's identity is displayed (if not restricted), and the user shall be able to decide whether to accept the communication or divert to a messaging system. The user shall be able to request media handling of the communication (e.g., media splitting to different destinations, media conversion).
5. The user is in a communication when he receives an incoming communication; he responds to the originating party that he will respond later. The user may request that the originating party's details (if not restricted) be stored with a reminder in user's profile.

Emergency Location with Voice Conversation, Navigation, and Picture Transfer

Person(s): Ma Beth, her children, and the pet dog Bobby

Situation: The family is out driving in the countryside, and they take a turn on the slippery country road a bit too fast. They slide down into the ditch. Bobby the dog, sitting in the back of the van, is hit by a heavy box of books on top of his left paw. It may be broken, and you can tell it certainly hurts from the loud yelps that come out in a rushed stream. The rest of the family is OK; they were all buckled up.

Solution: Ma Beth reaches for her communicator as soon as she has recovered from the initial shock. She calls 112 (911 or similar). The answer comes after 23 seconds, and the operator immediately confirms the identity and the location of the van. Ma Beth is a bit taken aback by this quick information and has to think for a while, then confirms the location as possibly correct. She then states the problem and gets connected to a vet that asks a few pertinent questions. She can show a close-up picture of the dog's left paw, and the vet confirms a possible (95 percent) broken leg just above the paw. He gives a few quick instructions and sends her a map of the closest emergency animal hospital. The map shows

her current position and soon displays the quickest way to get to the hospital. When they arrive there, Bobby is taken care of and things begin to look up. Even the kids are smiling now that the dog is calm and free from pain, and he looks so funny with his little cast.

Benefit(s): The initial call transfers emergency information to the operator automatically. This ensures minimum delay to correct action. The communicator transfers the picture that gives enough information to make a very accurate and fast assessment of the situation. Then the map transfer and display on the terminal, together with the current position, gives clear information and directions for Ma Beth to drive and make the right turns at every corner. In her half-shocked state, she can drive to the hospital without hesitation about where to go. This is very reassuring for all parties, including the dog who gets the fastest possible help.

Comments: The call is initially just a voice call but evolves with the best of positioning in emergency situations and navigational aid, together with picture and graphics transfer.

Application Sharing with Voice Commentary

Person(s): Marketing manager Rita and media expert Jones

Situation: The launch of a new campaign for some customers in London. Last-minute feedback indicates that one of the customers is expecting the latest gadget to be included, even if it is only a prototype. Rita knows it's not included in the presentation, and she has no information with her.

Solution: Rita calls Jones, the media guru they employed for design of their important presentations. He has the information and some pictorials. He sends them over into Rita's PowerPoint application, and they edit the new slide together as they discuss the textual information to be included.

Benefit(s): The process is extremely interactive and the session takes only five minutes, thanks to the broadband connection and the fact that they don't need to ping-pong the pictures and the text back and forth. (Emphasize mobile or fixed access as required.) The customer is happy, and a letter of intent is signed.

Comments: By adding voice and pictures to an interactive session, we achieve effectiveness and interaction, two desired components.

Global Wireline/Wireless Market Trends

Over the last few decades, telecommunication has proven to be the fastest developing industry in the market. This should be noticeable because of the increasing revenues of major telecommunications carriers and the huge number of new entrants to this market. According to Rappaport (2002), wireless communications did not have substantial market penetration until thirty-five years after its introduction. This delay could be attributed to the high costs of deployment and the technological challenges during the first decades of mobile telephone introduction.

The wireless market has experienced sharp growth during the last ten years. For instance, from 1999 to 2004, there was an explosion in the number of subscribers and the amount of sales. This growth is expected to continue,

and the number of wireless subscribers is expected to augment in the coming years. In fact, it is expected that by 2010, global wireless subscribers will exceed wireline subscribers. Figure 1 shows the number of worldwide mobile telephony subscribers in billions, as well as the percentage increase in subscriber population from 1991 to 2007. The corresponding information was taken from UMTS World (2006) and is summarized in the figure.

This growth is attributed to the fact that the consumer is more and more in need of mobile services and becoming more and more adapted to wireless technologies. These continuously increasing needs have driven an important change in the mobile sector: a shift toward the convergence of all networks and devices in mobile systems to an integrated architecture that supports multimedia

Figure 1: Population growth of worldwide subscribers

services (voice, image, video, and data). This refers to the ability to securely access any service on the network from any communicating device, any time and anywhere, with support for real-time transmission. Fortunately, this growth in the deployment of 3G wireless services has been accompanied by the fast development of low-cost and highly sophisticated mobile devices. According to the statistical handbook of the Wireless World Forum (2006), U.S. operator revenues will grow by another \$20 billion in 2007. The three main trends that drive revenue growth are:

- A 44 percent rise in the number of senior (fifty- to sixty-year-old) mobile owners by 2007, to 23.29 million
- A 28.2 percent rise in the number of young (ten- to fifteen-year-old) mobile owners by 2007, to 13.36 million
- A 68 percent increase in data revenues to \$17.5 billion by 2007, stimulated by rising short message service (SMS) usage.

Key Regulatory Issues and Standardization

The standardization of IMT-2000 platforms and technologies is not the activity of one single organization but of many standardization and research groups and committees (ITU 1998), including:

- Telecommunication Industry Association (TIA), United States
- Wireless Technologies and Systems Committee (WTSC), United States
- European Telecommunications Standards Institute-Special Mobile Group (ETSI-SMG)
- Association of Radio Industries and Businesses (ARIB), Japan
- Telecommunication Technology Committee (TTC), Japan
- Telecommunication Technologies Association (TTA), Korea

- Research Institute for Telecommunications Transmission (RITT), China

When the ITU communication standardization sector task group (TG) 8/1 called for radio transmission technology (RTT) proposals, various bodies submitted their proposals and those accepted were later organized into the IMT-2000 set of platforms (see Figure 2). For Europe, the ETSI-SMG proposed universal terrestrial radio access (UTRA) with versions frequency division duplexing (FDD; W-CDMA) and time division duplexing (TDD; time division synchronous code division multiple access [TD-SCDMA]). In China, the RITT proposed the TD-SCDMA. UTRA FDD (W-CDMA) was proposed by the Japanese ARIB and the Korean TTA, which also proposed cdma2000. Several proposals were presented to the ITU-R in the United States. The TIA proposed cdma2000 (evolution of CDMAOne), UWC-136 (evolution of IS-136), and wireless multimedia and messaging services (WIMS), based on W-CDMA. The WTSC presented the W-CDMA-North America (W-CDMA-NA), which was later merged with WIMS to form the wideband packet CDMA (WP-CDMA).

After the approval of ITU-R on the proposals above, two worldwide projects were established and given the names 3GPP (Europe) and 3GPP2 (North America); their purpose is to harmonize the activities between the different regions and standard bodies. This harmonization and consensus building is considered to be for the public good and benefits the manufacturer, operator, and customer. The first body, 3GPP, is responsible for the harmonization and standardization of the ETSI, ARIB, TTC, TTA, WTSC FDD, and WTSC TDD proposals. The other body, 3rd-Generation Partnership Project 2 (3GPP2), is responsible for those proposals of TTA and TIA that are cdma2000 based.

IMT-2000 Specifications

Within the IMT-2000 framework, five air-interface standards are defined for 3G systems. In fact, IMT-2000 can be thought of as a reference for different technologies

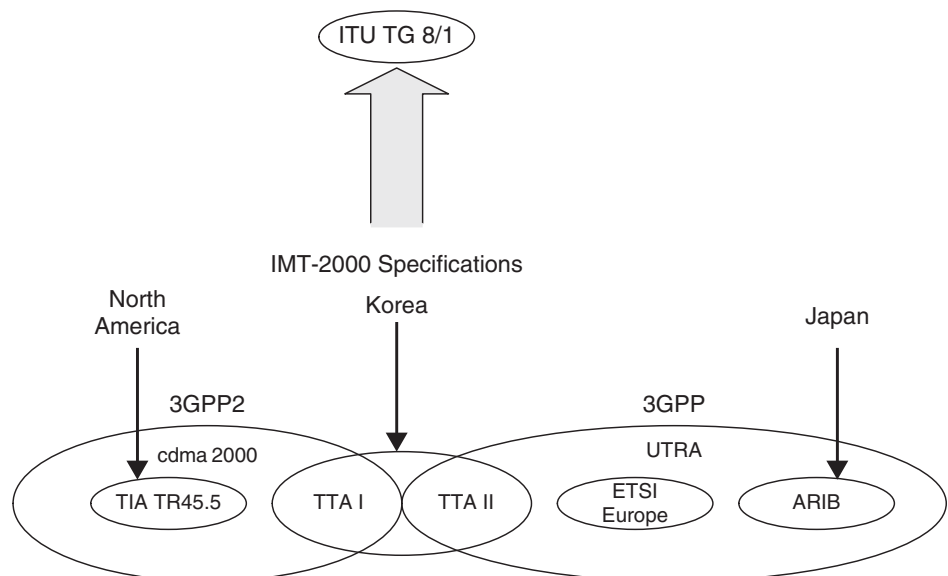

Figure 2: RTT proposals

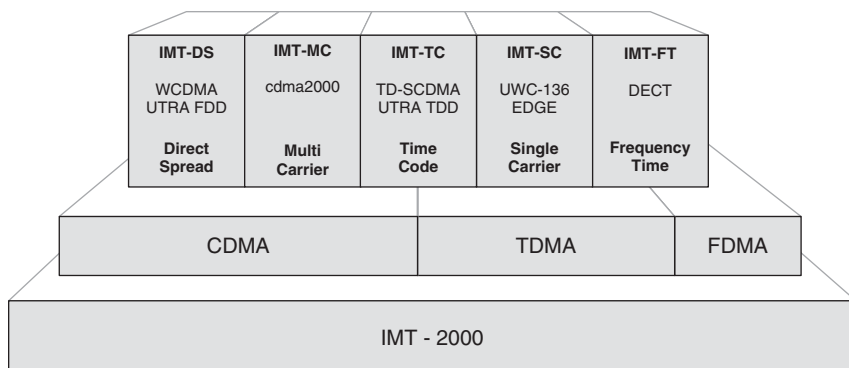

Figure 3: IMT-2000 standard platforms for 3G air interfaces

covering many frequency bands, channel bandwidths, and modulation techniques. The development of these standards and specifications is distributed via a number of international organizations and forums. Figure 3 shows the structure of the various platforms recommended by the IMT-2000 specifications. As seen in the figure, these competing radio access platforms are based on different technologies, which makes the harmonization process a difficult task. The five main standards are as follows:

UMTS (W-CDMA FDD): This is an IMT direct-spread (IMT-DS), CDMA-based technology. UMTS is also known as W-CDMA and is generally managed by the 3GPP organization (2006). This technology requires a pair of frequency bands (paired spectrum).

cdma2000: cdma2000 is an extension of the current 2G CDMA standard IS-95. It is managed by 3GPP2 (2006), a separate organization from 3GPP. This technology also requires a pair of frequency bands (paired spectrum). cdma2000 comes in a single carrier (1X) or multi-carriers (MX).

TD-SCDMA (UTRA TDD 1.28 Mcps option): This is an IMT time code (IMT-TC), also known as TD-SCDMA or the UTRA TDD 1.28Mcps option (which differs from the 3.84 Mcps option). This technology requires a single unpaired frequency band (unpaired spectrum).

UWC-136: UWC-136, also called time division multiple access single carrier (TDMA SC), is a standard proposal based on TDMA technology. UWC-136 is the extension to the current 2G TIA/EIA-136 technologies. This technology requires a pair of frequency bands (paired spectrum).

DECT: Digital enhanced cordless telecommunications (DECT) is a digital wireless technology that originated in Europe but is increasingly being adopted worldwide for cordless telephones, wireless offices, and even wireless telephone lines to the home. This technology requires a single unpaired frequency band (unpaired spectrum).

The key to the success of a standard is the availability of spectrum. WARC-92 specified the spectrum allocation for 3G systems. Figure 4 shows spectrum allocation in the major regions of the world according to IMT-2000. Europe and Asia use the frequency bands that WARC-92 allocated for IMT-2000 3G systems around 2 GHz. On the other hand, in the United States and Canada, the 2 GHz spectrum is unavailable for IMT-2000 because it was auctioned for operators using 2G mobile systems. This problem

persists in other countries as well, following the U.S. personal communication system (PCS) spectrum allocation. Accordingly, those countries will employ 3G services within the existing bands.

PROPOSED 3G SYSTEM

ITU and ETSI 3G Activities

ITU is an intergovernmental organization and a specialized agency of the United Nations with headquarters in Geneva, Switzerland. ETSI is a nonprofit association with headquarters at Valbonne, France. These two bodies signed an agreement in June 2002 for mutual cooperation and exchange of documentation (ITU/ETSI 2002). Although this cooperation is built on the basis of reciprocity, the ultimate advantage is the reduction of duplication in global efforts and the development of appropriate standards responsive to global market needs.

According to this agreement, each party has its own responsibilities. The ITU Radiocommunication Sector (ITU-R) is responsible, inter alia, for studying and issuing recommendations on radiocommunication questions. The ETSI undertakes prestandardization and standardization activities in areas common to telecommunications, information technology, and sound and television broadcasting, and is responsible for standardization in the whole field of telecommunications, including radio, broadcasting, and private telecommunications.

3G Harmonization Efforts

The IMT-2000 specification defines more than one technology. In addition, it asks for harmonization and compatibility among the different technologies. This interoperability, which would provide service to users over a seamless worldwide network, is one of the major objectives for IMT-2000. Accordingly, the various technology platforms shall be able to interact completely with one another. Moreover, user handsets will be universal—in other words, usable with the various technologies. Figure 5 shows the efforts toward this harmonization. In the figure, 3GPP and 3GPP2 are two different entities. However, they are now united and work cooperatively on standard development. At the time of this writing, 3G harmonization has not been achieved but hopefully will be forthcoming soon.

Proposed European 3G Systems Characteristics

The European activities toward 3G are piloted by the 3GPP. The proposed 3G system network architecture is IP based, a simplified version of which is shown in Figure 6. This IP-based architecture would have to support both stream and best-effort services. 3GPP essentially started with general packet radio service (GPRS) as the core packet network and overlaid it with call-control and gateway functions required for supporting voice over IP (VoIP) and other multimedia services (Patel and Dennett 2000).

The network offers different classes of services with varying quality of service (QoS) parameters. The divisions are based on the type of traffic, and the four classes are defined as follows:

- Conversational class (voice, video telephony, video-gaming)
- Streaming class (multimedia, video on demand, Webcast)

- Interactive class (Web browsing, network gaming, data-base access)
- Background class (e-mail, SMS, downloading)

The varying QoS parameters for all of these classes include bit error rate (BER), maximum transfer delay, and delay variation. The offered data rate depends on the environment:

- 144 kbits/s satellite and rural outdoor
- 384 kbits/s urban outdoor
- 2048 kbits/s indoor and low-range outdoor

Proposed North American 3G Systems Characteristics

The North American activities toward 3G are piloted by the 3GPP2. The proposed 3G system network architecture is a single network for all services, and a simplified

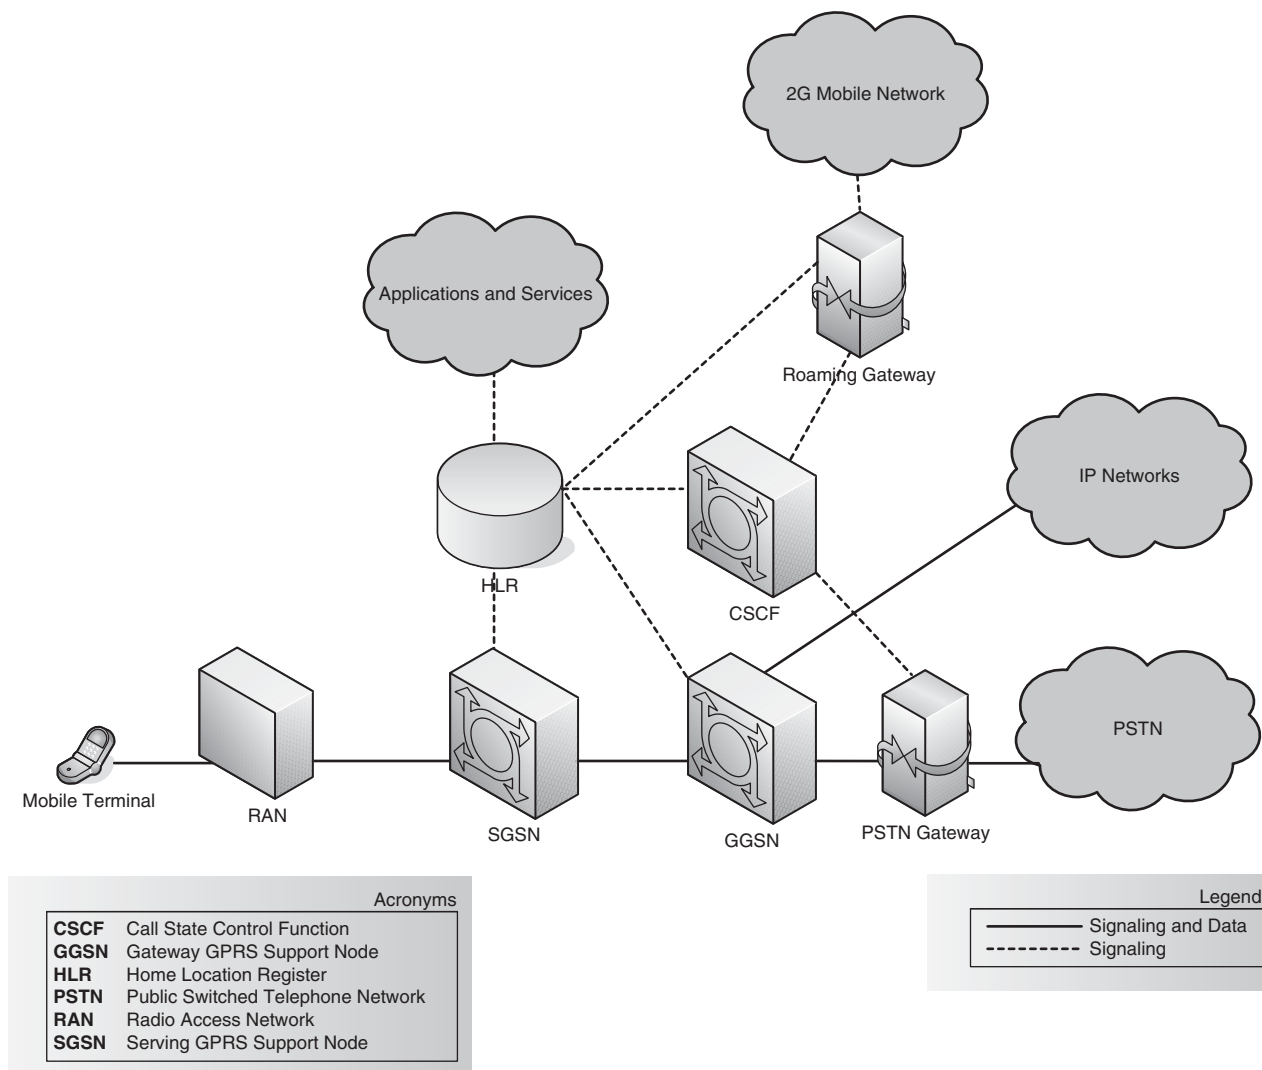

Figure 6: 3GPP proposed network

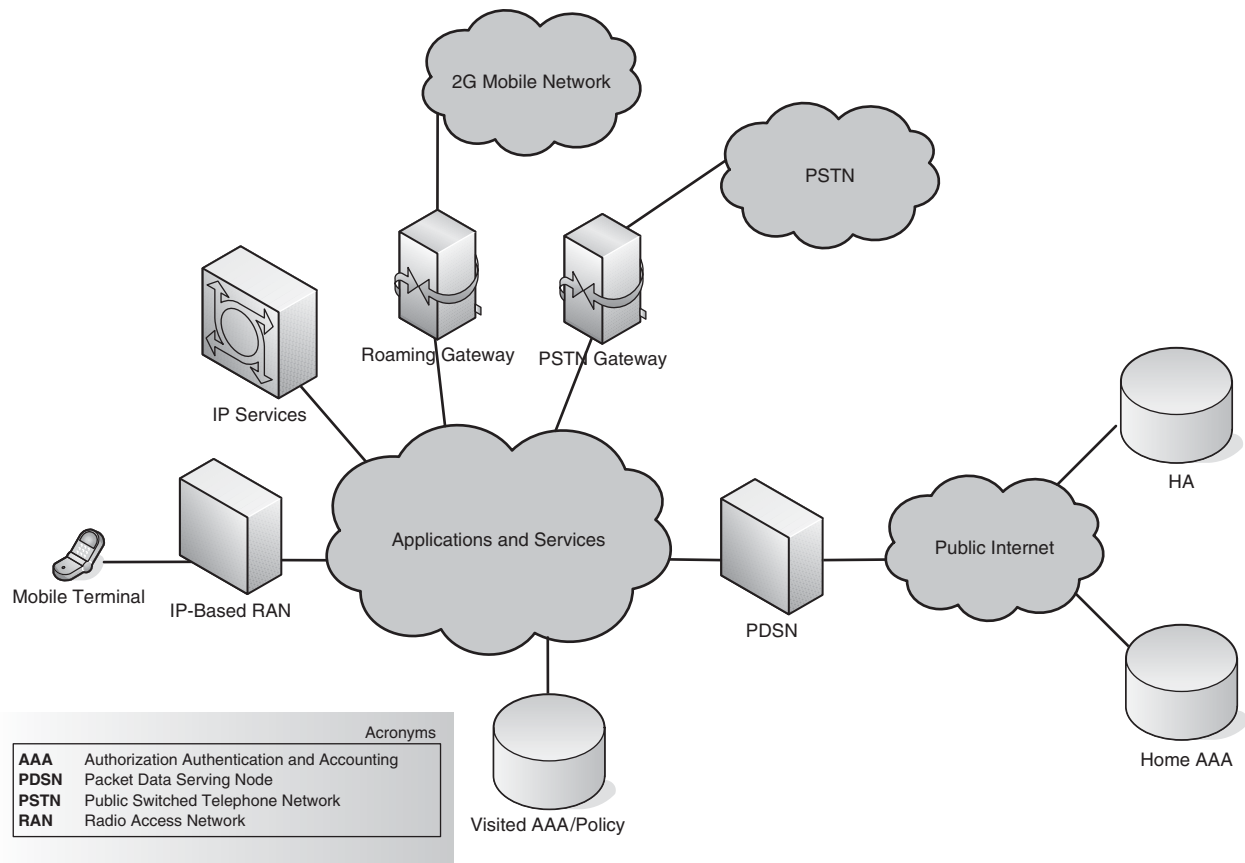

Figure 7: 3GPP2 proposed network

version is shown in Figure 7. This network offers end-to-end IP connectivity, distributed control and services, and gateways to legacy networks. 3GPP2 has created a new packet data architecture that builds on the CDMA 2G and 3G air-interface data services (Patel and Dennett 2000).

Proposed 3G Network Features

As mentioned in a 3G standard document (3GPP 2005), this new generation of mobile communications technology will create a world in which personal communications services should allow person-to-person calling, independent of location, the terminal used, the means of transmission (wired or wireless), or the choice of technology. Personal communication services should be based on a combination of fixed and wireless/mobile services to form seamless end-to-end service for the user.

The prime objectives of this new technology are:

1. To provide a single integrated system in which the user can access services in an easy-to-use and uniform way in all environments.
2. To allow differentiation among service offerings of various networks and home environments.
3. To provide a wide range of telecommunications services including those provided by fixed networks and requiring user bit rates of up to 2 Mbps, as well as services special to mobile communications. These services are supported in residential, public, and office environments, as well as in areas of diverse population densities. These services are provided with a quality comparable to that provided by fixed networks, such as integrated services digital network (ISDN).
4. To provide services via handheld, portable, vehicular-mounted, movable, and fixed terminals (including those that normally operate connected to fixed networks) in all environments (e.g., residential, private domestic, and different radio environments), provided that the terminal has the necessary capabilities.
5. To provide support of roaming users by enabling users to access services provided by their home environments even when roaming.
6. To provide audio, data, video, and particularly multimedia services.
7. To provide for the flexible introduction of telecommunication services.
8. To provide the capability to support universal personal telecommunications (UPT).
9. To provide within the residential environment the capability to enable a pedestrian user to access all services normally provided by fixed networks.
10. To provide within the office environment the capability to enable a pedestrian user to access all services normally provided by private branch exchanges (PBXs) and local area networks (LANs).

11. To provide a substitute for fixed networks in areas of diverse population densities, under conditions approved by the appropriate national or regional regulatory authority.
12. To provide support for interfaces that allow the use of terminals normally connected to fixed networks.

EVOLUTION FROM 2G-BASED SYSTEMS TO 3G

An Overview of Cellular Communications

The term *cellular* follows from the fact that a geographic coverage area is partitioned into hexagonal cells. The main reason behind this partitioning is frequency reuse. Co-channel cells—those using the same channels for voice or control—are always safely spaced to avoid interference. Figure 8 shows an example cell partitioning in which the cluster size is three—the number of cells over which no

Figure 8: Clusters and cells in a cellular coverage area

frequency reuse occurs. This increases the system capacity (i.e., the number of subscribers) without risking the quality of service.

The major components in a cellular system are the mobile station (MS), which is the subscriber unit, the base station (BS), which is the transmission/reception antennae tower, and the mobile switching center (MSC), which manages call establishment and teardown. These components are shown in Figure 9. The BS communicates with many MSs at a time, whereas the MS communicates with only one BS. Each MS transmits data to the BS over the reverse channel (uplink), and receives data from the BS over the forward channel (downlink). The data could be voice or control, and the channel allocation is temporary. For more information on cellular system architecture, please refer to the chapters entitled “Cellular Communications Channels” and “Cellular Telephony” in this handbook.

Handoff

Figure 9 shows an MS, a car in this case, crossing the boundaries of one cell into another. If the MS is doing the crossing during a call, this means that the call should be dropped, or that the MS gets on a new channel in the new cell. Whenever a BS detects a weak signal from the MS it automatically requests a handoff, in which the system, without user intervention, assigns a new channel to the MS in the new cell.

Power Control

Prolonging battery life has always been a main concern of mobile telephony. Power control schemes target

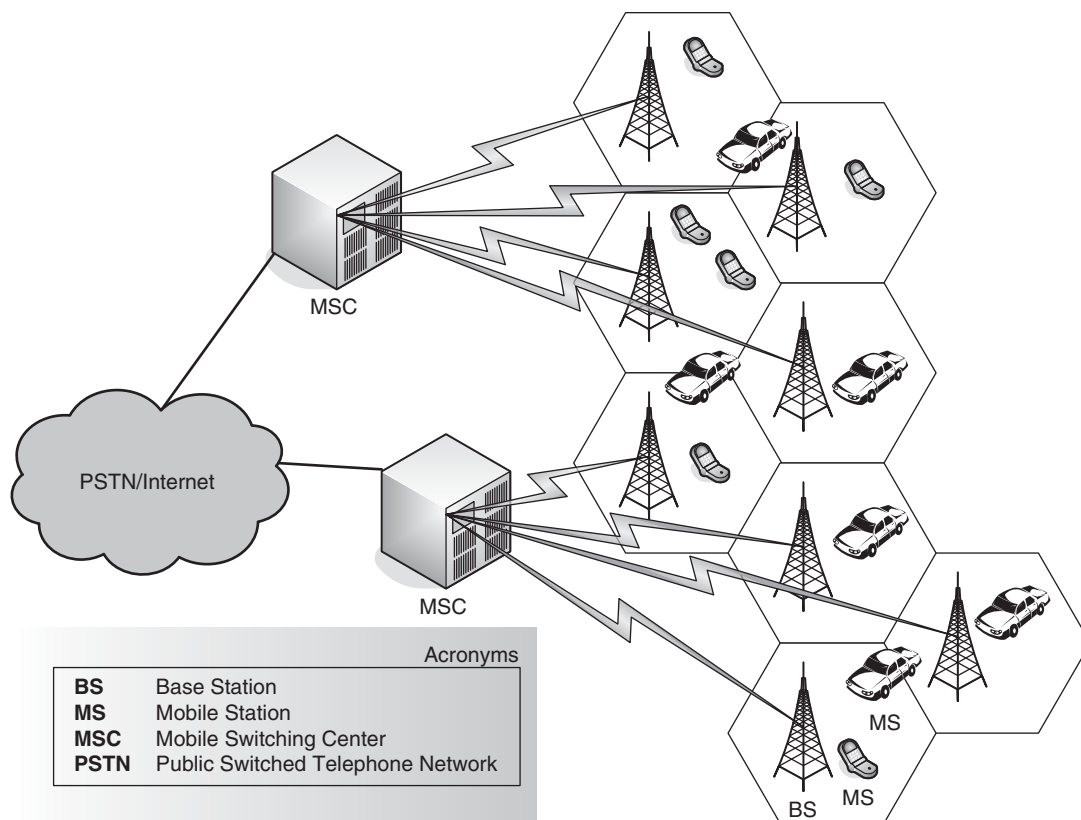

Figure 9: Cellular system architecture

this issue. In fact, base stations continually control the amount of power transmitted from mobile stations while maintaining a good quality signal. This not only extends battery life but also decreases interference caused by the transmissions of mobile stations.

Access Technologies

In any wireless communication system, the air interface needs to be accessed by multiple users simultaneously. Accordingly, the radio spectrum needs to be shared in some scheme to allow multiple subscribers to send and receive data at the same time. The major access techniques are:

Time division multiple access (TDMA): TDMA is a digital access technology that allows multiple users to access a single radio frequency channel simultaneously

without interference through time sharing. Each user is assigned a specific time slot for transmission.

Frequency Division Multiple Access (FDMA): FDMA is an access technique in which the radio frequency bandwidth is divided into chunks, and the user is allocated one single channel at a time. FDMA has the advantage of controlling interference by assigning nonadjacent channels to adjacent users. Figure 10 compares FDMA and TDMA by showing how time and frequency are partitioned to allow multiple user access.

Code Division Multiple Access (CDMA): CDMA permits multiple users to occupy the same frequency spectrum or medium simultaneously. Accordingly, different users can be active all the time because each user has a uniquely different code than other users (Figure 11). The codes are shared by both the mobile station and

Figure 10: FDMA and TDMA compared

Figure 11: CDMA concept

the base station, and are called pseudo-random code sequences. Base stations in the system distinguish themselves from one another by transmitting different portions of the code at a given time. Besides this concurrent access capability, CDMA has the advantage of enhanced immunity to interference and multipath effects.

Differences between 1G, 2G, and 3G Systems

Many wireless communications exist, and many are being developed. Tables 1 through 3 summarize the most common paging, cordless, cellular, and PCS standards used in North America, Europe, and Japan.

Mobile communications in the form of analog cellular networks, or what were later called *1G systems*, started to appear in the late 1970s and early 1980s, although

radio telephone systems existed before then. The first technology to be tested was the advanced mobile phone service (AMPS) technology, which was deployed in the largest U.S. cities. At the same time, AMPS was being deployed in Japan, and another technology called Nordic mobile telephone (NMT) was also being implemented in a number of European countries. A few years later, the British total access communications system (TACS) was launched. TACS was based on AMPS but featured minor variations.

The various 1G systems worked fine during the initial years of deployment. Unfortunately, a few years later, a couple of critical weaknesses started to demand the attention of operators as well as users. The mobile networks were quickly flooded with an unexpectedly huge number of subscribers. This growth abnormality was accompanied by critical security holes.

Table 1: Major Mobile Radio Standards in North America

Standard	Type	Year of Introduction	Multiple Access	Frequency Band	Modulation	Channel Bandwidth
AMPS	Cellular	1983	FDMA	824–894 MHz	FM	30
NAMPS	Cellular	1992	FDMA	824–894 MHz	FM	10
USDC	Cellular	1991	TDMA	824–894 MHz	$\pi/4$ DQPSK	30
CDPD	Cellular	1993	FH/Packet	824–894 MHz	GMSK	30

Source: Rappaport (2002).

Research soon focused on the development of a new system that solved the security and capacity pitfalls: the 2G systems that appeared first in the market in the early 1990s. 2G systems were the first digital cellular networks. Many technologies were recommended and even deployed, all of which targeted the support of more sophisticated services coupled with the guarantee of high immunity against fraud as well as the support of more users. Moreover, 2G introduced the capability of short message service and text delivery.

2G systems varied in band usage (800, 900, 1800, and 1900 MHz bands) and offered data rates in the range of 9.6 kbps to 14.4 kbps. The three leading technologies of 2G are the global system for mobile communications (GSM), interim standard 95 (IS-95) CDMA, and IS-136 TDMA.

Approaching the year 2000, wireless voice services had almost reached their peak (Collins and Smith 2001). The goal of wireless operators soon became the application of carrier-grade services on wireless networks. With the efforts of the ITU and its IMT-2000, 3G systems were introduced, the main features of which are packet-switched network, always-on connectivity, value-added services, and global roaming. These 3G systems followed the 2G systems, such as GSM, cdmaOne, and TDMA, while enhancing the data rates to 384 kbps and more with the potential to support 2 Mbps data rates. In addition to this high throughput, 3G offered advanced converged services (multimedia services) with performance enhancements to the current quality of service (higher speech quality). Moreover, this platform became global in two scopes: (1) in terms of connecting terrestrial and satellite networks together with fixed networks, and (2) in terms of service consistency and commonality around world operators (e.g., *virtual home environment* [VHE] roaming). The main differences among the three generations can be summarized as follows:

1. First generation was analog based and, in addition to suffering from security problems, had efficiency and functionality shortcomings.
2. Second generation was a low bit-rate digital technology and was based mainly on circuit-switched voice transmission.

3. Third generation is an evolutionary step up to a fully packet-switched system that supports higher bit rates as well as a collection of multimedia and data services.

European and North American Wireless Systems

IS-95 (or CDMAOne)

IS-95, also known as TIA-EIA-95 and J-STD-008, is a 2G CDMA-based, digital, cellular standard pioneered by Qualcomm; cdmaOne is its brand name. It is a direct sequence (DS) wideband spread-spectrum technology platform that enables multiple users to access the same radio channel—hence the term *multiple access* in CDMA. IS-95 uses CDMA technology to send voice, data, and signaling data (such as a dialed telephone number) between mobile telephones and cell sites. This technology has grown quickly and has been employed widely in the United States and Asia.

Figure 12 shows the network architecture of the IS-95 platform. This is a simplified view of the network to fit both versions: IS-95/A and IS-95/B. The first element seen is the base transceiver station (BTS), with which the user communicates. There is one BTS in each cell of the network. This tower contains radio transceivers and antennas, a processor, channel cards, and other equipment necessary for providing service in the cell. The next unit is a special type of switch called the *base station controller* (BSC), which groups and controls BTSs. Several BSCs are then grouped with an MSC. This is a higher level of switching but one that includes interfacing and interworking functions (connections to the public switched telephone network [PSTN]). Besides providing routing and switching services, this unit is important because it provides many functions, including subscriber and device management and registration, location updating and call handoff, signaling, and billing information collection. The MSC is interfaced with a database called the home location register (HLR). This database stores and maintains subscriber information—mainly, as the name implies, it stores the user location.

Figure 12: IS-95 network architecture

GSM

GSM is a 2G platform for mobile communications and is significant for being the basis of more advanced systems like GPRS, enhanced data rates for GSM evolution (EDGE), and UMTS. Moreover, it is the most widely accepted radio communication around the world. GSM is the European standard for digital cellular communications. Originally designed to operate in the 900 MHz frequency band, and later deployed in this spectrum, it is also deployed in the 1800 and 1900 bands. The GSM radio channel is 200 kHz wide, and it is a TDMA system (mobile users share the medium on a time division basis) with FDD (separate uplink and downlink frequency bands). GSM's major functional blocks are the switching system (SS), the base station subsystem (BSS), and the operations and support system (OSS). These will be explored shortly.

Figure 13 shows the architecture of the GSM BSS. The system is composed of the BTS and the BSC, and the interface between those two subsystems is known as the Abis interface. The BTS contains the equipment for transmitting

and receiving radio signals (which provide the interface with the mobile station), antennas, and equipment for encrypting and decrypting communication with the BSC. The other part is the BSC, which is the subsystem with the intelligence and processing power. It provides a number of management, operation, and maintenance functions for mobile stations in the coverage area of the BTSs and for the overall network. The handset, in GSM jargon, is called the mobile station (MS). This station is composed of two parts: the mobile equipment (ME), which is the electronic mobile device, and the subscriber identity module (SIM). The latter is a small electronic card that maintains the key to identifying a mobile phone service subscriber's identity, as well as subscription and authentication information, preferences, and text messages. The equivalent of an SIM in UMTS is the universal subscriber identity module (USIM).

The network architecture of the GSM system is shown in Figure 14. Beginning from the BSC previously discussed, the next node is the transcoder and rate adaptation unit

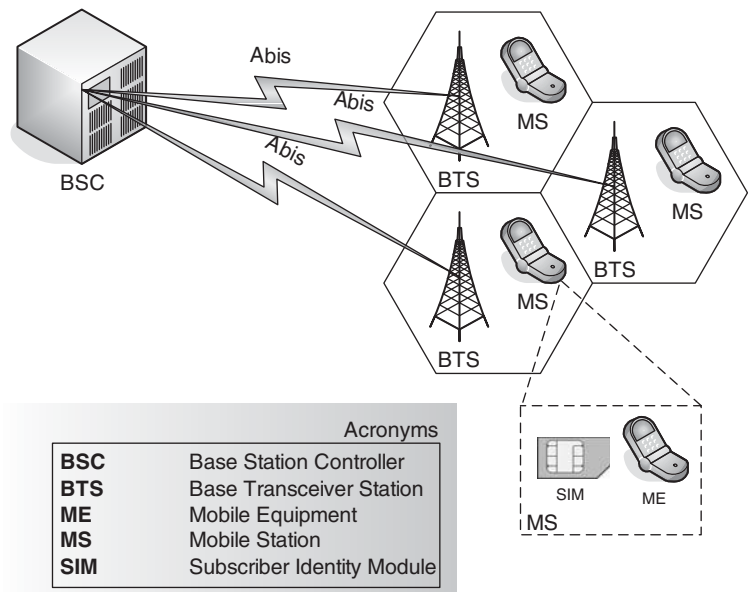

Figure 13: GSM base station subsystem (BSS)

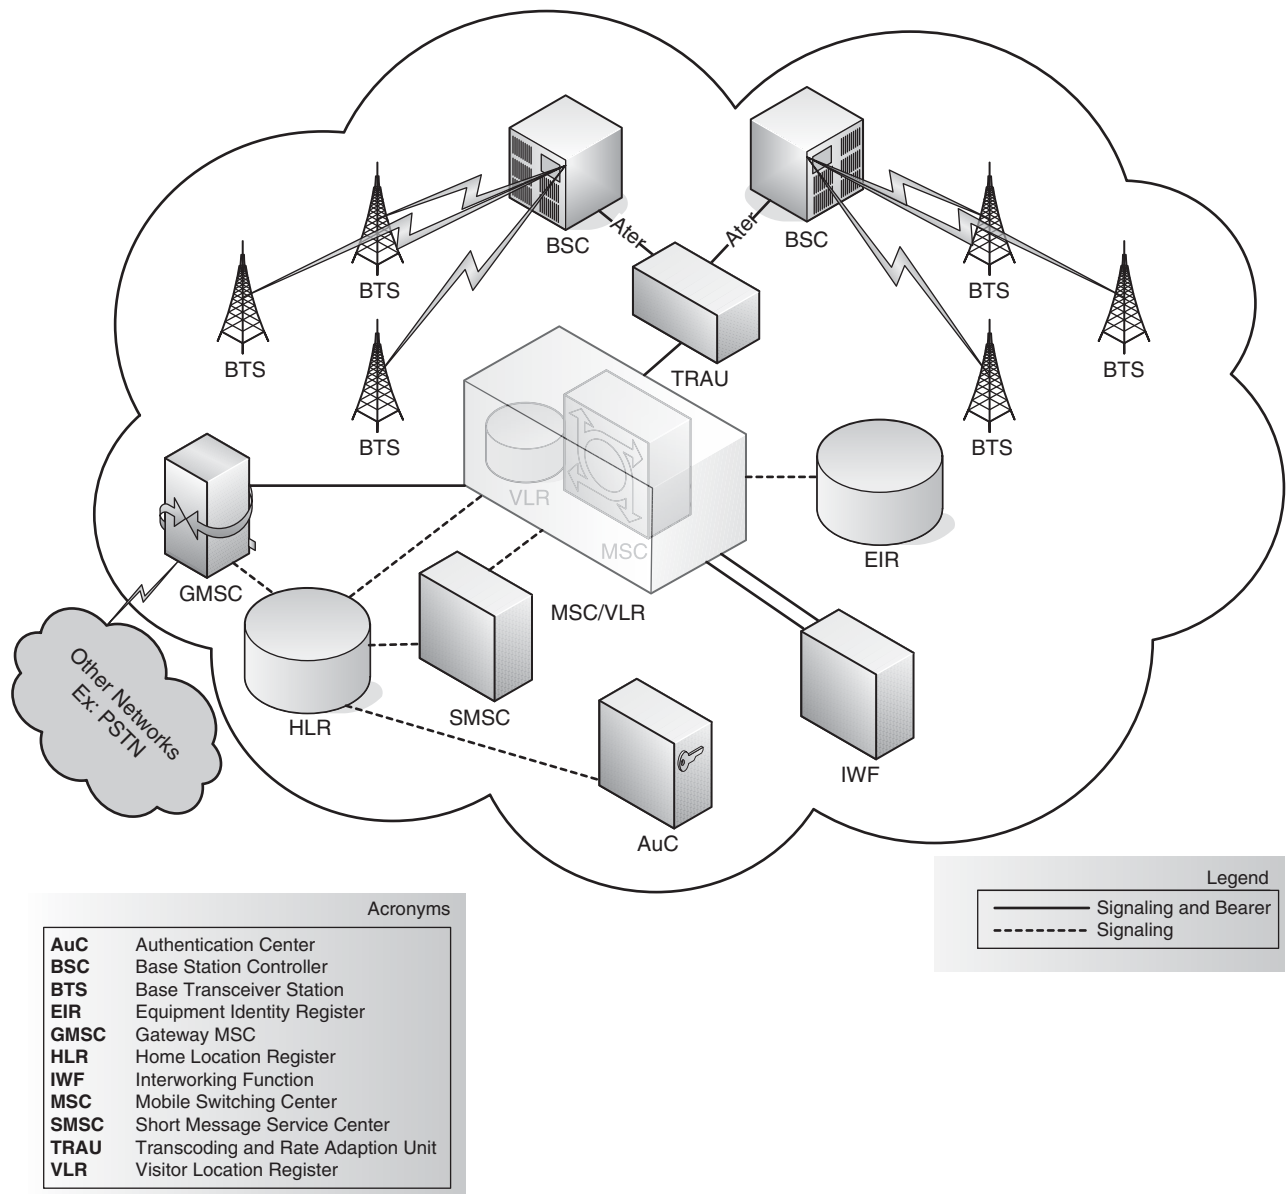

Figure 14: GSM network architecture

(TRAU). It is the role of TRAU to convert the coded speech from GSM standard (12.2 or 13 kbps) to pulse coded modulation (PCM) standard (64 kbps), and vice versa. This helps to interface with the PSTN, which uses the PCM for speech coding. As shown in the figure, the interface between the TRAU and the BSC is known as Ater interface. A switch called the MSC then groups one or more BSCs. Call initiation, routing, and teardown functions, as well as many other important functions of the whole network, are the responsibilities of this switch. A database node called the visitor location register (VLR) helps the MSC achieve its functionality by storing information about all the mobiles that are currently under the jurisdiction of the MSC to which they are attached. The MSC node is connected to the BSC through an interface called the A-interface.

Figure 14 also shows a node called the home location register (HLR). This is another database for storing subscriber information—primarily information about services for which the subscriber has subscriptions. Furthermore, this database receives queries about the location of a certain subscriber. Two subsystems send such queries. The first one is the gateway mobile switching center (GMSC), which interfaces the GSM network to the PSTN network. The second is the short message service center (SMSC), which stores and forwards short data messages to and from subscribers. We can also see another node called the authentication center (AuC), which is also a database but stores subscriber-specific authentication information—primarily the subscriber authentication key (Ki)—as well as different authentication algorithms. For the user to be authenticated, the information stored in the AuC should match the information stored on the user's SIM card.

The figure also shows a unit known as the equipment identity register (EIR), which contains white, grey, and black lists of international mobile equipment identity (IMEI) numbers. This number uniquely identifies mobile equipment, and thus the GSM operator can grant access to specific equipment (white list) or block its access (black list). Equipment listed in the grey list may or may not be barred. Besides the GMSC, there is another unit that is important and noteworthy in the interworking context: the interworking function (IWF), which is a modem bank that helps support circuit-switched and fax services.

GPRS

Although GSM enhanced wireless communications through data services, the data rate was as slow as 9.6 kbps. It was not until general packet radio service that packet-switched data services with data rates around 64 kbps were introduced to the wireless world. In addition to increased data rates, packet switching itself is an enhancement in availability and better resource utilization. GPRS uses the same channel width of 200 kHz, like GSM divided into eight time slots; therefore, they share the same radio frequency (RF) resources. The difference is that the total number of slots that a subscriber's mobile equipment can gain access to varies. Furthermore, there are various channel coding schemes for each channel. Accordingly, the user can have access to variable data rates, given that the packet-switched paradigm itself introduces diversity to the data rate. Figure 15 shows the network

architecture of the GPRS standard. It looks similar to the GSM network, except for some new nodes and interfaces as shown in the figure.

The first new node seen is the packet control unit (PCU), which helps the BSC to support packet-switching functionality through packet assembly, reassembly, and scheduling. This could be considered the air-interface access part of the packet-switching services of GPRS. The other part is packet routing, which is achieved through the serving GPRS support node (SGSN). The SGSN acts as a routing switch like the circuit-switched MSC but in the packet-switched domain. The interface of the GPRS network with the other packet-switched networks is supported through the gateway GPRS support node (GGSN). For instance, for a transmission of data from GPRS to the public Internet, GPRS data packets are tunneled inside IP packets from the SGSN to the GGSN. The charging gateway function (CGF), together with the billing system, interacts to accomplish the billing operations and maintain the user-billing data. As shown in the figure, many interface standards are imposed by the GPRS standard for links between different node types. For instance, the Gb interface defines the interaction between an SGSN and a BSC.

EDGE

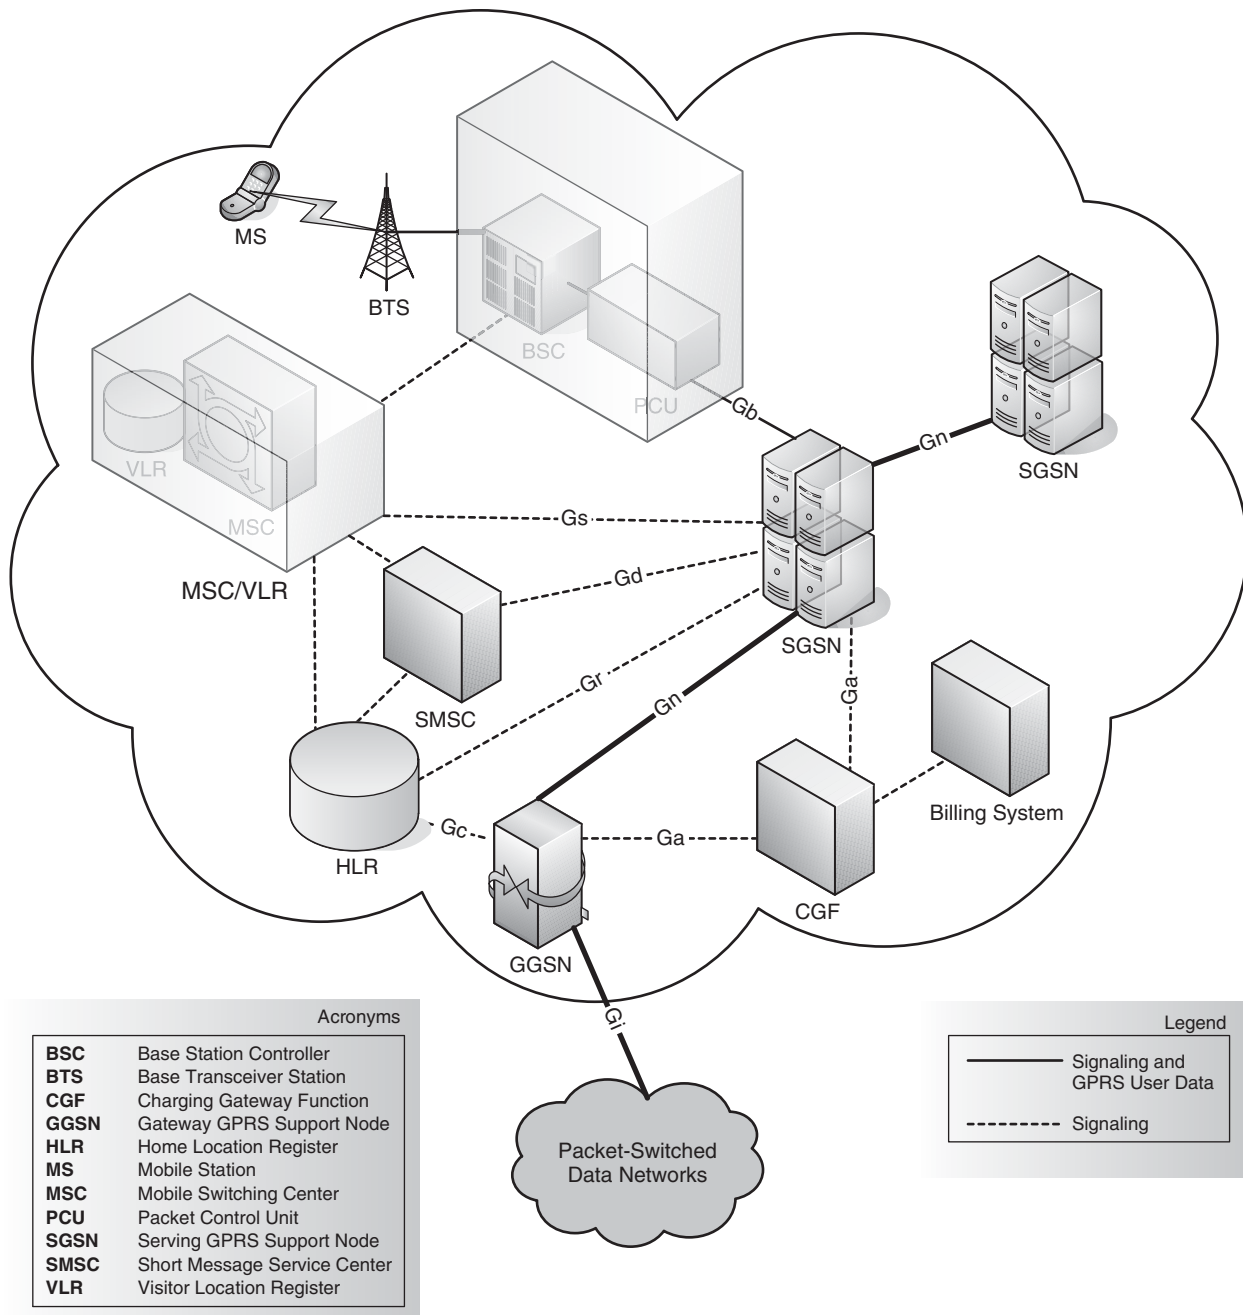

Enhanced data rates for GSM evolution, or EDGE, is the step in the evolutionary path to 3G from GSM platforms and IS-136 TDMA. As mentioned previously, EDGE is considered to be a 2.75G system, or a pseudo-3G system, since it almost fulfills the 3G requirements but is not marketed as such. In fact, proponents of EDGE consider it more favorable than proposed 3G standards; it is sufficient in terms of the throughput the current user needs, much less costly than the 2 GHz 3G since no new spectrum allocation is required, and there is no need for the 5 MHz channel, having compressed the 200 kHz.

EDGE, like GSM and GPRS, uses the same channel width of 200 kHz divided into eight time slots, but with data throughput exceeding that of GSM and GPRS. The key improvement is in the air-interface modulation scheme, whereas the network core is almost the same as that of GPRS. EDGE uses 8-phase shift keying (8-PSK) in addition to the Gaussian minimum shift keying (GMSK) used in GPRS. In 8-PSK, the bandwidth is better utilized, with a tradeoff of less immunity to noise. Accordingly, there is always a variation in the EDGE network throughput, and the user may sense the difference. Depending on the location of the user and the BTS, as well as the RF conditions, the appropriate modulation and channel-coding schemes are chosen. A change in modulation scheme, intended to utilize the available bandwidth and increase throughput, results in less immunity to noise. On the other hand, using a strict coding scheme gives high immunity to noise but adds more overhead and, hence, decreases the overall throughput.

3G Systems

UWC-136

Universal wireless communication-136 was the first proposal submitted by the United States in response to the

IMT-2000 initiative. It was developed by the Universal Wireless Communications Consortium (UWCC) as a 3G wireless standard based on (TDMA) technology that offers backward compatibility with 2G TDMA-based IS-136 as well as GSM systems. In terms of evolutionary paths, UWC-136 is the proposed 3G destination for the 2G TIA/EIA-136 technologies. Furthermore, it is also the 3G destination platform appropriate for the 1G AMPS. The technology allows a wide range of frequencies—from 500 MHz to 2.5 GHz. The platform's radio transmission technology proposes a low-cost incremental and evolutionary deployment path for both AMPS and TIA/EIA operators.

cdma2000

Code division multiple access 2000 is the proposed evolution for cdmaOne 2G platforms and makes up a substantial part of the IMT-2000 specifications. Because the main objective of 3G systems is the support of multimedia services for fixed and mobile users, the key improvement on cdmaOne is the addition of data services to the voice service. Accordingly, this raises the need for various upgrades to existing components as well as the introduction of new ones. The major component that needs to be added is the packet data server—the packet data serving node (PDSN), shown in Figure 16. This figure shows a

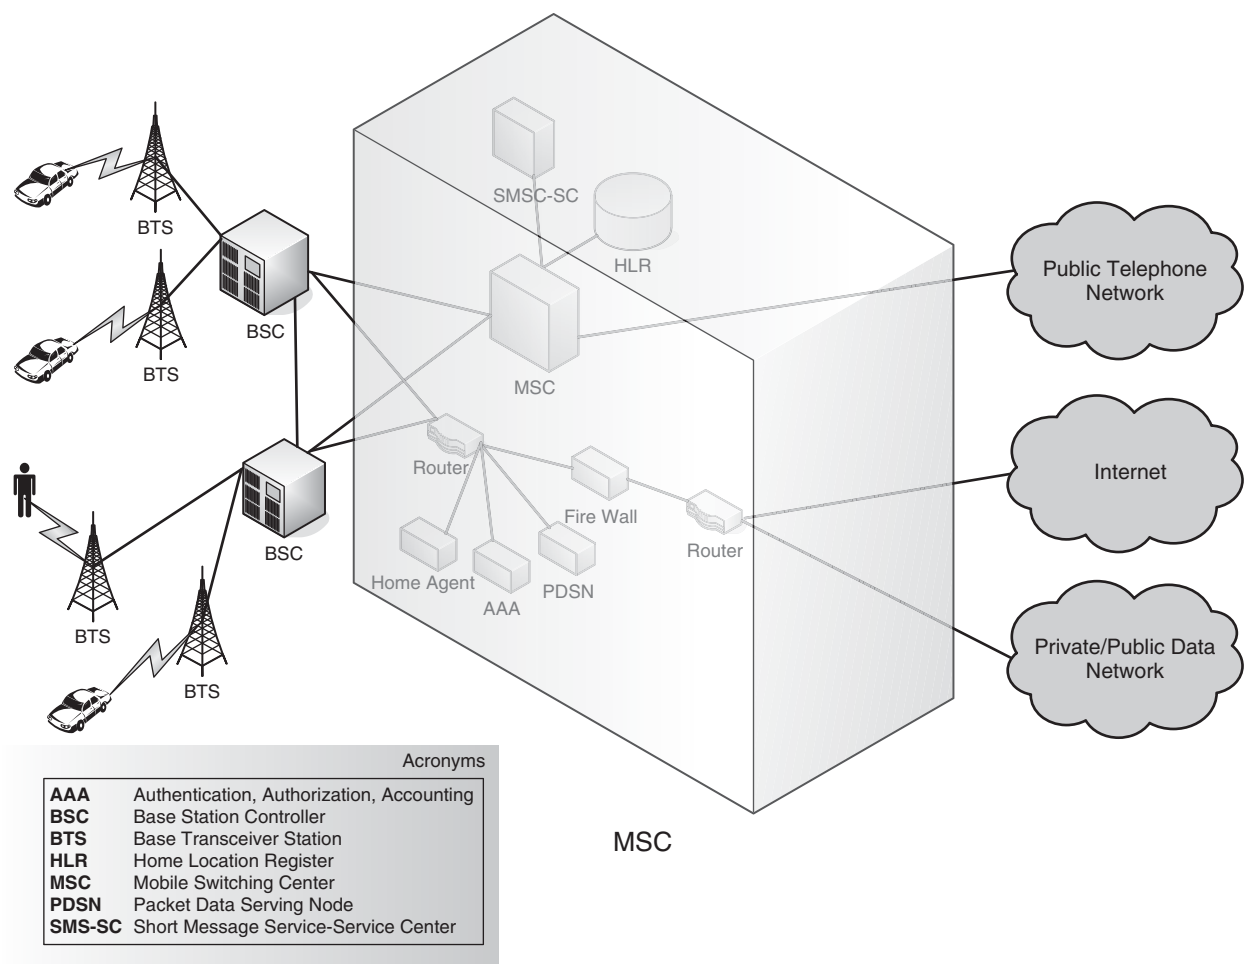

Figure 16: cdma2000 network architecture

Figure 17: cdma2000 IX and 3X

simplified version of the cdma2000 network architecture. In fact, the cdma2000 network comes in two flavors, centralized and distributed, depending on the system characteristics sought.

Many times the name cdma2000 is accompanied by 1X or 3X (cdma2000-1X or cdma2000-3X). Figure 17 shows

the spectrum specifications for cdma2000. The basic idea is this: cdmaOne is built over a bandwidth of 1.25 MHz, and cdma2000 is an enhancement of either the same bandwidth (1X) or multiples of it (3X). Hence, the operator makes the choice of either using the designated spectrum of 5 MHz or the existing 1.25 MHz.

cdma2000 1xRTT: The first version of cdma2000 provides data rates for a maximum of 144 kbps. This is known as cdma2000 1xRTT (RTT stands for radio transmission technology). This version uses a single 1.25 MHz channel—hence, the 1x in the name.

The next version is cdma2000 1xEV (1xEV-DO and 1xEV-DV), which is completely backward compatible with cdma2000 1xRTT. It is a two-phase evolution.

cdma2000 1xEV-DO: The first phase is cdma2000 evolution-data optimized (1xEV-DO), originally evolution-data only. The first company to deploy cdma2000 1xEV-DO was SK Telecom in Korea, in January 2002. It is now deployed in many places around the world. This standard, as the name implies, is data only; to support voice, cdma2000 1x channels have to be used. It is defined by IS-856 and is similar to cdma2000 1x but with high data rate (HDR) capability. The first revision, Rev. 0, supports data rates up to 2.5 Mbps in the downlink and 153 kbps in the uplink. Rev. A supports data rates up to 3.1 Mbps in the downlink and 1.2 Mbps in the uplink. Besides boosting data rates, this revision also supports IP packets. The latest revision, Rev. B, supports downlink data rates up to 4.9xN Mbps and uplink data rates up to 1.8xN Mbps, where N is the number of 1.25 MHz carriers occupied by the system.

cdma2000 1xEV-DV: The second phase is cdma2000 evolution-data voice (1xEV-DV), which integrates voice and data on the same carrier with data rates up to 3.1 Mbps on the downlink and 1.8 Mbps on the uplink. Even though it followed cdma2000 1xEV-DO, many carriers have chosen to deploy the 1xEV-DO.

cdma2000 3xRTT: After the cdma2000 1xEV versions comes the cdma2000 3xRTT. This version uses three 1.25 MHz CDMA channels. It is currently under development, and no carrier has deployed it yet.

UMTS/W-CDMA

W-CDMA is a wideband direct-sequence code division multiple access (DS-SS). This means that the user data is spread over a wider bandwidth through multiplication by quasi-random bits called *chips*. These chips are bits derived from the CDMA spreading codes. Through the use of the appropriate chip rate, the carrier bandwidth of 5 MHz is achieved. Moreover, the operator is able to combine multiples of this 5 MHz with appropriate spacing (guard bands). This gives the channel an increased multipath diversity. W-CDMA comes in two flavors: FDD and TDD. In the former, FDD, separate carriers are used for uplink and downlink. TDD, however, is based on the use of one carrier but with time sharing between uplink and downlink channels. An added feature of W-CDMA is its adaptable user data rates; each user is allocated a time frame, and those frames differ in their data rate capabilities in order to meet the utmost packet data service.

TD-SCDMA

As a contribution to the IMT-2000, the TD-SCDMA RTT proposed by China Wireless Telecommunication Standards group (CWTS) was approved by the ITU in 1999, and technology is being developed by the Chinese Academy of Telecommunications Technology (CATT) and Siemens.

TD-SCDMA uses TDD. That means that the uplink and downlink spectrum is assigned flexibly, depending on the type of information being transmitted. When asymmetrical data like e-mail and the Internet are transmitted from the base station, more time slots are used for downlink than for uplink. A symmetrical split in the uplink and downlink takes place with symmetrical services like telephony (TD-SCDMA Forum 2006).

TD-SCDMA adopts high-edged technologies such as smart antenna, software radio, joint detection, baton handover (handover that occurs without interruptions, as in soft handover but with more capabilities; see 3GPP Technical Specification Group Radio Access Network Working Group 2 [1999] for more information), and high-speed transmission technology for downlink packet data. Compared with other mobile systems, TD-SCDMA boasts outstanding technological benefits:

- High spectrum efficiency: TD-SCDMA, with the highest spectrum efficiency (given the low chip rate compared to other standards; 3GPP Technical Specification Group Radio Access Network Working Group 2 [1999]), better supports dense services in populated areas. It is capable of making full use of a fragmented spectrum, and it effectively alleviates spectrum resource shortage and limitations for the carriers.
- High capacity: The adoption of high-edged technologies dramatically lowers interference and increases system capacities.
- Highly suitable for operators' asymmetrical data services: Because TD-SCDMA is competent for dynamically adjusting data transmission rates with uplink and downlink, it suits the handling of asymmetrical IP data services.
- Low costs: The adoption of smart antenna technology decreases transmission power in the TD-SCDMA system and dramatically lowers the cost of the system products (Datang Mobile 2005).

Evolution Paths for 2G Systems to 3G Systems

Beginning in the early 1980s, the first generation of mobile communication 1G dominated with its main variants:

1G Standards

1. AMPS (800)
2. TACS (900)
3. NMT (900)
4. SMR (800 and 900)

The specialized mobile radio (SMR) system is a “walkie-talkie” type service used by taxis and delivery trucks. The numbers between brackets—for instance, the 900 in NMT (900)—denotes the frequency band used in MHz. In the early 1990s, a shift in technology from analog to digital systems was proposed, and the 2G system was introduced. Soon afterward, there arose the need for a migration path from 1G to 2G. Operators using the TACS and NMT (900) systems chose to migrate to GSM (900) systems; portion

of the operators using AMPS migrated to IS-136 TDMA (800), and the rest moved to IS-95 CDMA (800). SMR operators migrated to the integrated digital enhanced network (iDEN) system that was proposed by Motorola. As shown in Figure 18, which shows the proposed evolution paths from 1G to 3G systems, the second generation featured four main systems, each one implemented in varying frequency bands.

2G Standards

1. IS-136 TDMA system in the 800 and 1900 MHz bands
2. IS-95 CDMA system in the 800 and 1900 MHz bands
3. GSM system in the 900, 1800 and 1900 MHz bands
4. iDEN system in the 800 and 1500 MHz bands

3G systems were proposed around the year 2000, together with an interim generation called 2.5G, or the evolution generation, which built up to 3G and involved an overlay

of higher-capacity data transmission capability to existing 2G digital wireless networks. The major 2.5G systems are:

2.5G Standards

1. GPRS
2. EDGE
3. cdma2000 1X-RTT

It is worth noting here that a subset of these standards is referred to as 2.75G systems. The term 2.75G—which was never officially specified—is used to describe systems that fall between 2.5G and 3G systems. Those systems either do not meet the 3G requirements but are marketed as if they do (e.g., the non-multi-carrier cdma2000), or they do meet the requirements but are not marketed as such (e.g., the EDGE system that provides 3G packet data services on GSM networks). As shown in Figure 18, GSM and TDMA operators migrated to GPRS and EDGE systems, and CDMA operators migrated to cdma2000 1X-RTT.

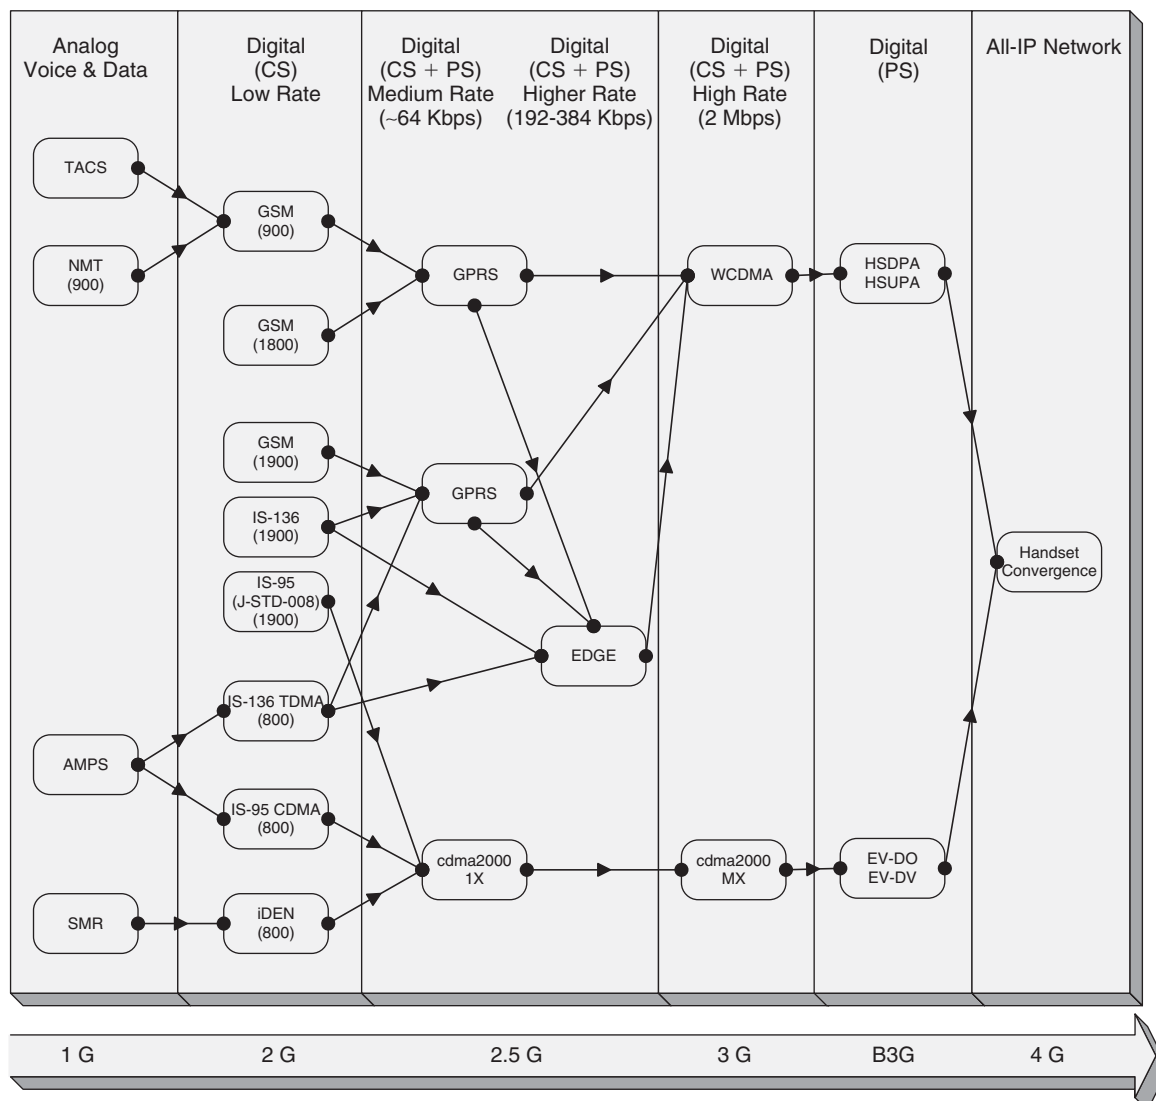

Figure 18: Proposed evolution paths (B3G: beyond 3G; CS: circuit switched; PS: packet switched)

When it comes to the migration from 2G—or even from 1G—to the 3G systems through the evolution generation 2.5G, the operator has to make the decision about which path to use. Regardless of the platform targeted, the operator has to face major issues: capacity, clarity, coverage, compatibility, and cost. The operator also has to decide on a strategy for the migration process, and those strategies typically involve either an overlay approach (no new spectrum allocation required, given an existing 2G platform) or a spectrum segmentation approach (separate radio frequency spectrum allocation needed). The fundamental enhancement of 2.5G over 2G systems was the introduction of the packet-switched data services coupled with increased speeds up to 384 kbps.

Figure 18 shows the two dominant 3G technologies: W-CDMA and cdma2000. One may wonder why only two platforms are discussed and given attention here, when we mentioned earlier that there are five standards proposed by IMT-2000. The fact is that the majority of wireless operators are targeting one of these two platforms as their future 3G platform. W-CDMA encapsulates the UTRA FDD and UTRA TDD discussed previously and is considered the choice for GPRS/EDGE (GSM-based) operators. On the other hand, cdma2000 is considered the choice for the 2G IS-95 (cdmaOne) operators and the 2.5G cdma2000 1X-RTT operators, both of which are CDMA based.

UMTS LAYERS AND CHANNEL STRUCTURES

Universal mobile telecommunications service is a category of 3G systems that groups all W-CDMA-based 3G air interfaces evolving from GSM platforms. The radio access for UMTS, known as universal terrestrial radio access (UTRA), comes in two flavors: UTRA FDD and UTRA

TDD. UMTS, which is the European initiative, provides advanced communications capabilities integrated with personal and terminal mobility to meet the user and service requirements of the twenty-first century.

UMTS offers support to multimedia services, which is the capability of delivering two or more media components within one call. The standard also enables the user of a single terminal to establish and maintain several connections simultaneously. UMTS also supports universal personal telecommunications, which is a feature that enables the user to access services via any terminal, irrespective of geographic location and networks utilized. To enable number portability, an international mobile user number (IMUN) is allocated to each new user at the start of a UMTS subscription. Moreover, users should be able to move a subscription from one home environment to another without changing the IMUN provided that the new home environment offers service in the same geographic domain (3GPP UMTS 1999).

UMTS Architecture and Interfaces

Figure 19 shows the network architecture of UMTS, or what is called the core network (CN). The various components of the CN are shown together with the defined interfaces between these components. The system comprises interconnected networks, both circuit-switched and packet-switched for voice and data services. Figure 19 shows the higher-level paradigm. Basically, the circuit-switched network contains the MSC and the gateway MSC; the packet-switched network contains mainly the SGSN, the GGSN, the domain name server (DNS), the dynamic host configuration protocol (DHCP) server, the packet charging gateway, and firewalls. In summary, there are components that carry the circuit-switched (CS) roles (e.g., MSC and VLR), components that carry the packet-switched (PS) roles (e.g., SGSN and GGSN), and

Figure 19: UMTS architecture

components that serve both parts (e.g., HLR.) In addition, several other subsystems are crucial to the operation of the CN; one example is the network management system, which applies to billing and general management.

UMTS Releases

The first release was Release 99 (R99), which was mainly an enhancement to the circuit-switched voice network and GPRS data network with the UMTS radio access network (UTRAN) (3GPP 2006). This resulted in achieving higher bandwidth, macrodiversity in handover, and support for QoS classes. The next release was Release 4 (R4), in which the circuit-switched voice network was replaced with either an ATM or an IP core network. Moreover, network-assisted location services and broadcast services were covered by R4. Release 5 (R5) was characterized by the addition of IP multimedia services (IMS), more flexible radio access network (RAN), and the high-speed downlink packet access (HSDPA). This improved throughput (end users are offered up to 14.4 Mbps in the downlink), latency (round-trip delay as low as 60ms), and capacity (data capacity is increased by a factor of 5). Major advantages of HSDPA are:

- High-speed downlink shared channel (HS-DSCH)
- Transmission time interval (TTI) of 2 ms
- Fast data traffic scheduling
- Adaptive modulation and coding (AMC)
- Fast hybrid automatic response request (HARQ) techniques (UMTS Forum 2006).

As for Release 6 (R6), improved uplink performance is achieved through high-speed uplink packet access (HSUPA), which mainly enhances coverage and throughput and reduces delay. More capabilities were added to the network in R6, including:

- Network resource sharing
- More IMS services
- Multimedia broadcast and multicast service (MBMS)—many users in parallel
- WLAN interworking
- Multiple-input multiple-output (MIMO)—multiple antennas used

Following high-speed packet access (HSPA)—which is a major improvement in performance—are HSPA+ and long-term evolution (LTE). These collectively will offer new services, including: voice over IP, multi-user gaming, and high-resolution video (UMTS Forum 2006). In order for the 3GPP system to cope with the rapid growth in IP data traffic, the packet-switched technology utilized within 3G mobile networks requires further enhancements. The high-level objectives of the move to an all-IP network (AIPN) and the drivers that are forcing this change are as follows:

- Universal seamless access: An AIPN should allow users to connect to services from a variety of device types and access systems. This should come about through

the use of common protocols, addressing schemes, and mobility management mechanisms. The users may not need to know the access system used. Access systems may be selected and changed according to service needs and availability.

- Improved user experience: An AIPN should provide users with better quality. This should include rapid network selection, rapid call or session setup times, low voice-call delay, and fast data transmission.
- Reduction of cost: An AIPN should deliver a cost reduction for AIPN operators in relation to the cost of existing networks.
- Flexibility of deployment: AIPN operators should be able to build and dimension their network according to the needs of their users. The AIPN design should be scalable and should not preclude the option to use and interwork with 3GPP-defined circuit-switched domains and legacy handsets as appropriate. The AIPN design should also provide an evolution path from previous releases of the 3GPP system. This will ensure that AIPN operators can introduce an AIPN and continue to make the best use of existing network elements (3GPP AIPN 2005).

Layer Structures and Functions in UTRA

Figure 20 shows the logical layers and structure of the UTRA network. The lowest layer is the physical layer. Among the various functions of this layer are:

- RF processing, spreading, scrambling, and modulation
- Coding and decoding for error correction
- Power control
- Timing advance
- Soft handover execution

The interface of higher layers with the physical layer is the medium access control (MAC) layer. The role of this layer is to interface upper and lower layers through the mapping of logical to physical channels. The next level up is the radio link control (RLC) layer, which has different roles that include:

- RLC connection establishment and release
- Error detection
- Ensuring error-free delivery through acknowledgments
- In-sequence delivery
- Unique delivery
- QoS management

This layer offers the higher layer of both acknowledged and transparent transport services. The former means that erroneous packets are automatically retransmitted, and the latter means that they are discarded. The layer above RLC is the packet data convergence protocol (PDCP), which provides the interface between the user data and lower layers. In other words, it operates on the user data to render it in the format expected by the lower layers; this satisfies the encapsulation of lower layers. Another subtle function above the RLC is the broadcast/multicast control (BMC), which refers to message broadcasting within the

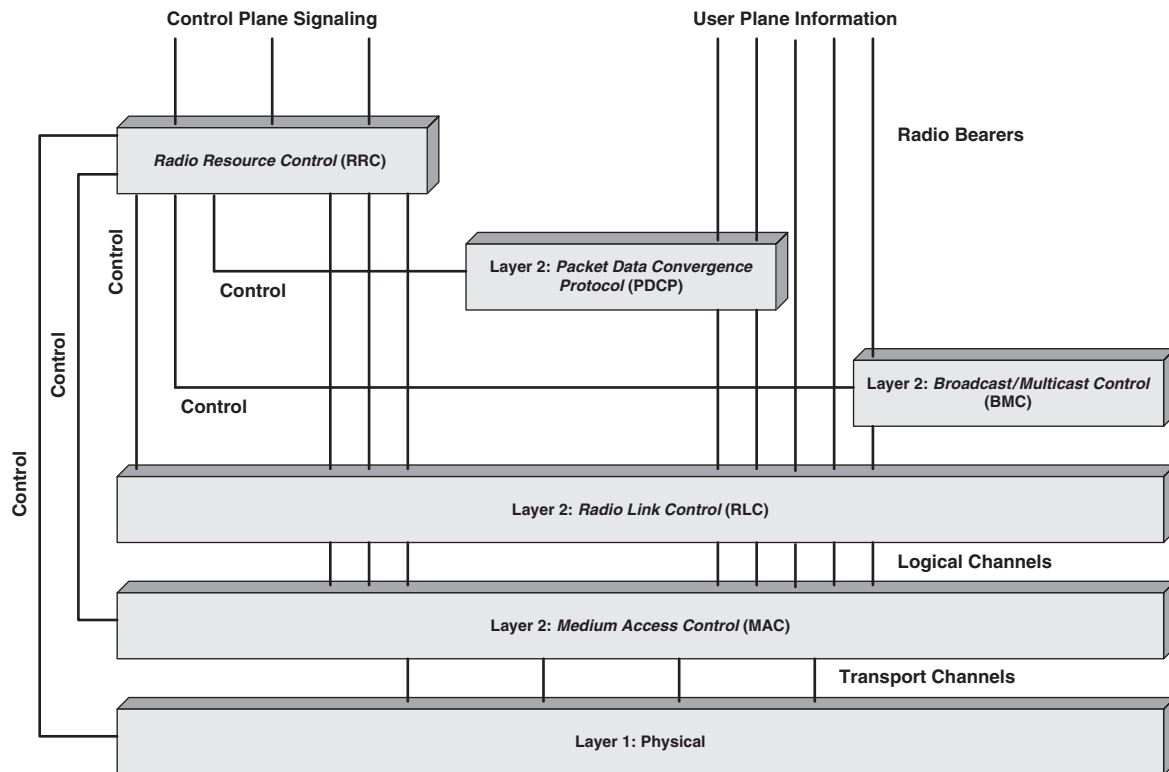

Figure 20: UMTS layers

cell, as in news or warnings. The last component—and the most important—is the radio resource control (RRC), which acts as the brain of the whole system. It comprises the processing power of the system and does the control and management jobs while connected to all layers with control lines. The RF resource allocation decisions are made at the RRC, but it has many other roles, including:

- Broadcasting of system information
- Signaling for connection initiation
- Allocation of bearers
- Measurement reporting
- Mobility management
- QoS management

Transport, Physical, and Logical Channel Identification and Mapping in UTRA

The layers already discussed collectively form an organized set of channels: logical, transport, and physical. As can be inferred from the name, physical channels are inherent in the physical layer. The MAC layer has multitransport channels, whereas the logical channels are the only way to get to the RLC layer. Furthermore, these different channels are connected through mappings of successive channel levels: logical-transport mapping and transport-physical mapping.

Transport Channels

There are two types of transport channels: common and dedicated. The common channel is shared among all users,

but it can be used to transfer data to all users (broadcast) or to a single user (unicast). All channels are common except for one: the dedicated channel (DCH). Table 4 summarizes the various UTRA transport channels and their functionalities.

Physical Channels

There are two sets of physical channels: channels that are mapped with upper-layer channels for interfacing and channels that are not mapped and are functional only in the physical layer. The physical layer itself is identified by different parameters: frequency, scrambling code, channelization code, duration, and phase. The different defined physical channels are described in Table 5.

Besides the paging indicator channel (PICH), indicator channels include the acquisition indicator channel (AICH), the access preamble acquisition indicator channel (AP-AICH), and the collision detection/channel assignment indication channel (CD/CA-ICH). UMTS physical channels also include the dedicated physical data channel (DPDCH), the dedicated physical control channel (DPCCH), and the CPCH status indication channel (CSICH). Figure 21 shows the mapping between physical and transport channels.

Logical Channels

Table 6 displays the logical channels, which are the communication channels between the RLC and the MAC layer. These channels have to do with the data transmitted rather than how it is transmitted. There are two types of logical channels: control and traffic channels.

Table 4: UTRA Transport Channels

Name	Description	Type	Functionality
DCH	Dedicated Channel	Dedicated	Used to send large amounts of data in long sessions
RACH	Random Access Channel	Common	Used for signaling; small amounts of data are sent through the uplink
BCH	Broadcast Channel	Common	Data are sent from the cell to all users in the cell through the downlink
PCH	Paging Channel	Common	Used to page a given UE through the downlink
FACH	Forward Access Channel	Common	Used to send control data to the user through the downlink
CPCH	Uplink Common Packet Channel	Common	Similar to RACH but supports the sending of more data
DSCH	Downlink Shared Channel	Common	Similar to FACH but with higher data rate and the support of unicast or multicast

Table 5: UTRA Physical Channels

Name	Description	Functionality
SCH	Synchronization Channel	The base station transmits on this channel, and the UE detects the signal for correct synchronization
CPCH	Common Pilot Channel	Always transmitted by the base station for the terminal to make measurements for handover or cell reselection
Primary CCPCH	Primary Common Control Physical Channel	Used on the downlink to create the BCH channel
Secondary CCPCH	Secondary Common Control Physical Channel	Used on the downlink to carry the FACH and PCH channels
PRACH	Physical Random Access Channel	Used in the uplink to carry the RACH channel
PCPCH	Physical Common Packet Channel	Used in the uplink to carry the CPCH channel
PDSCH	Physical Downlink Shared Channel	Used on the downlink to carry the DSCH channels
PICH	Paging Indicator Channel	Used to carry the paging indicators

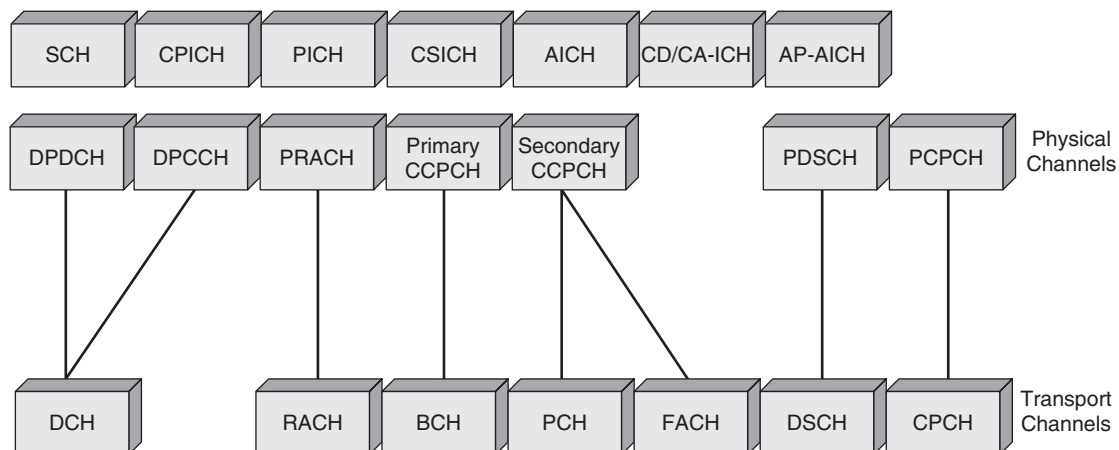

**Figure 21:** Physical-transport channel mapping

Figure 22 shows the mapping between logical and transport channels.

Channel Spreading and Modulation in UTRA

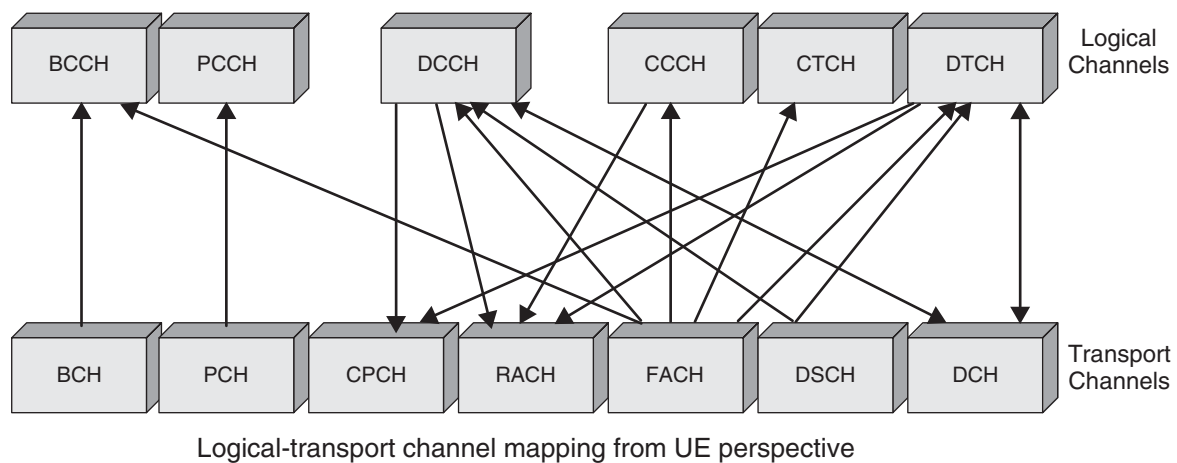

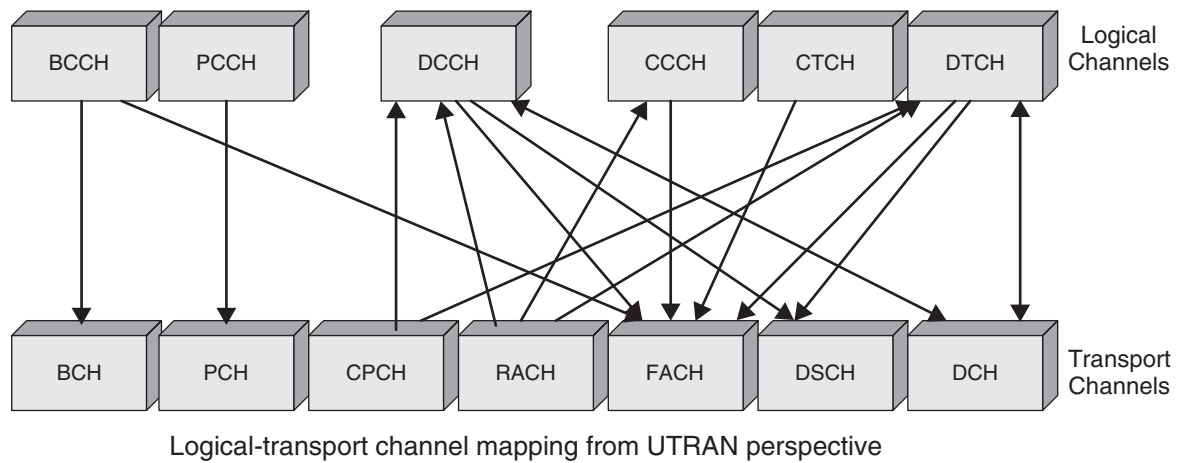

Three important steps take place before transmission from user equipment (UE) occurs. The data undergo

spreading, also called channelization, followed by scrambling and modulation. First, different data streams from the same user are distinguished by applying the spreading code. Then, data streams from different UEs are distinguished by applying the scrambling code. Finally, the data resulting from this two-stage coding are modulated

Table 6: UTRA Logical Channels

Name	Description	Type*	Functionality
BCCH	Broadcast Control Channel	CCH	Used for downlink transmission of system information
PCCH	Paging Control Channel	CCH	Used for the paging of an MS across one or more cells
DCCH	Dedicated Control Channel	CCH	Used in the uplink by terminals to access the network without connection
CCCH	Common Control Channel	CCH	Bidirectional point-to-point control channel between the MS and the network for sending control information
DTCH	Dedicated Traffic Channel	TCH	Point-to-point channel dedicated to the UE for the transfer of user data
CTCH	Common Traffic Channel	TCH	Point-to-multipoint unidirectional channel for the transfer of user data to all UEs or a single UE

*CCH = control channel; TCH = traffic channel.

**Figure 22:** Logical-transport channel mapping

before being transmitted. Figure 23 shows this process for the uplink, and Figure 24 shows it for the downlink. Both codes applied to the data stream are at the chip rate of 3.84 Mcps. At the receiving end, the signal is first descrambled to separate different UEs, and then the channelization code is applied to recover the original stream.

As mentioned previously, the physical layer has multiple physical channels. These channels are distinguished during transmission by the application of the appropriate channelization codes. For instance, if the UE is transmitting data and control information, then the two channels can be easily multiplexed and demultiplexed. Figure 23

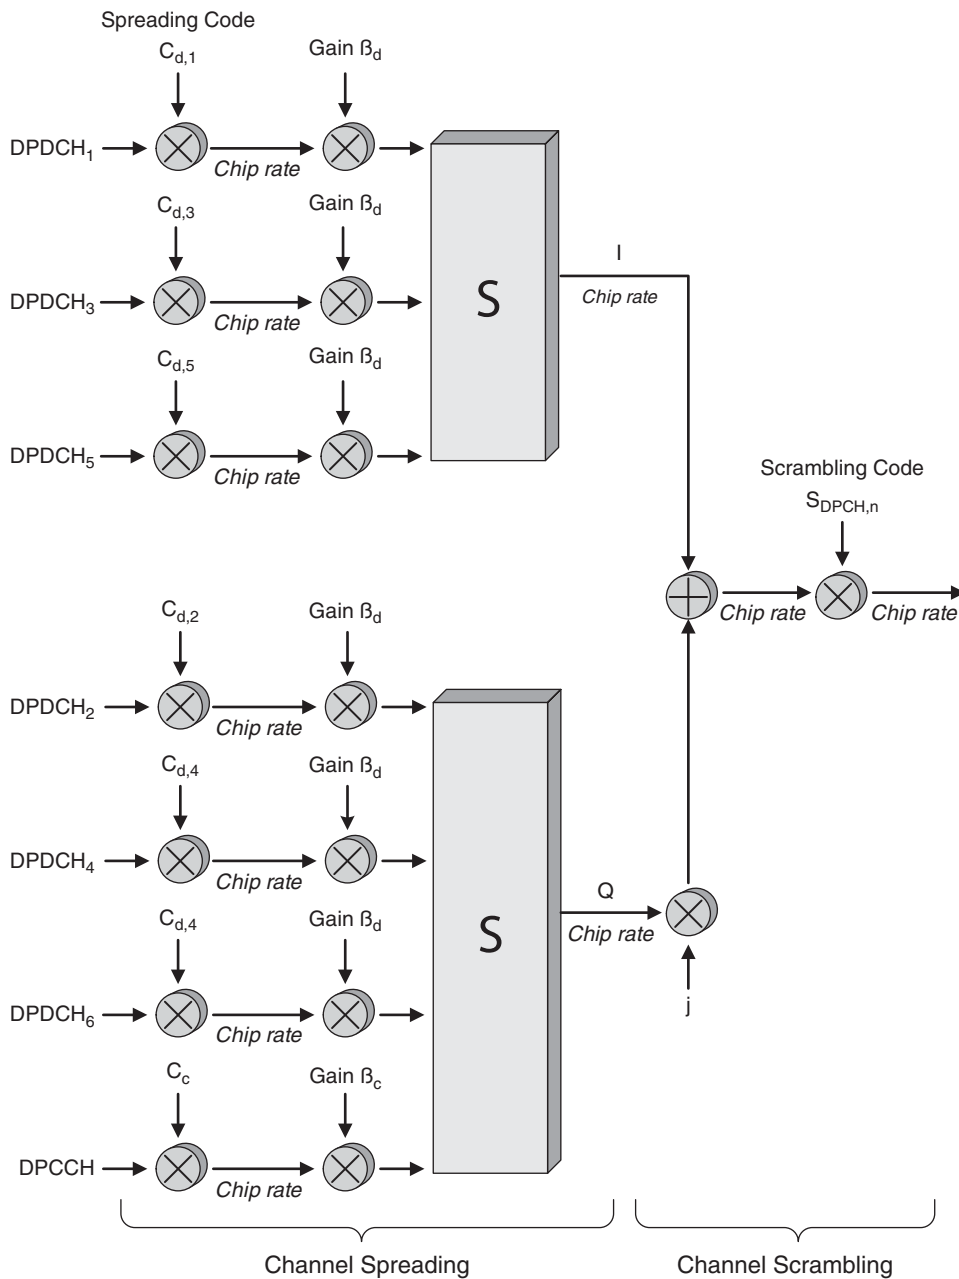

Figure 23: Uplink spreading and scrambling

shows a sample scenario; the UE is transmitting, in the uplink, data on the DPDCH as well as control information on the DPCCH. The user can use up to six DPDCHs depending on the required data rate. $C_{d,1}$, $C_{d,2}$, ..., $C_{d,6}$, and C_c are the channelization codes applied to the various channels, which spread the data at the chip rate. The odd data channels are spread (with $C_{d,1}$, $C_{d,3}$, and $C_{d,5}$) and weighted (with a gain factor of B_d), creating the stream of real bits (In-phase, or I). The even data channels are spread (with $C_{d,2}$, $C_{d,4}$, and $C_{d,6}$) and weighted (with a gain factor of B_d), then added to the control channel, which is spread (with C_c) and weighted (with a gain factor of B_c), creating the stream of imaginary bits (Quadrature phase, or Q). The real bits are added to the imaginary bits multiplied by j (where $j = \sqrt{-1}$), creating a stream of complex-valued chips at the chip rate. This resulting stream is then subjected to the complex-valued scrambling codes. There are two types

of scrambling codes—long and short—with 2^{24} possibilities for each type. The two types of scrambling code are pseudo-random; the long codes have a length of 38,400 chips and the short codes have a length of 256 chips.

Figure 24 shows what happens on downlink channels. The stream to be spread is split using a serial-to-parallel converter. The even bits go to the I branch, whereas the odd bits go to the Q branch. The same channelization code is used to spread the two branches. A complex-valued stream is created when the I branch (real bits) is added to the jQ branch (imaginary bits) and is then subjected to a complex pseudo-random scrambling code. The scrambling codes used in the downlink are similar to the uplink codes but are of different lengths. In the case of downlink, the purpose of the scrambling codes is to differentiate the streams originating from different base stations (or different cells). The number of scrambling codes

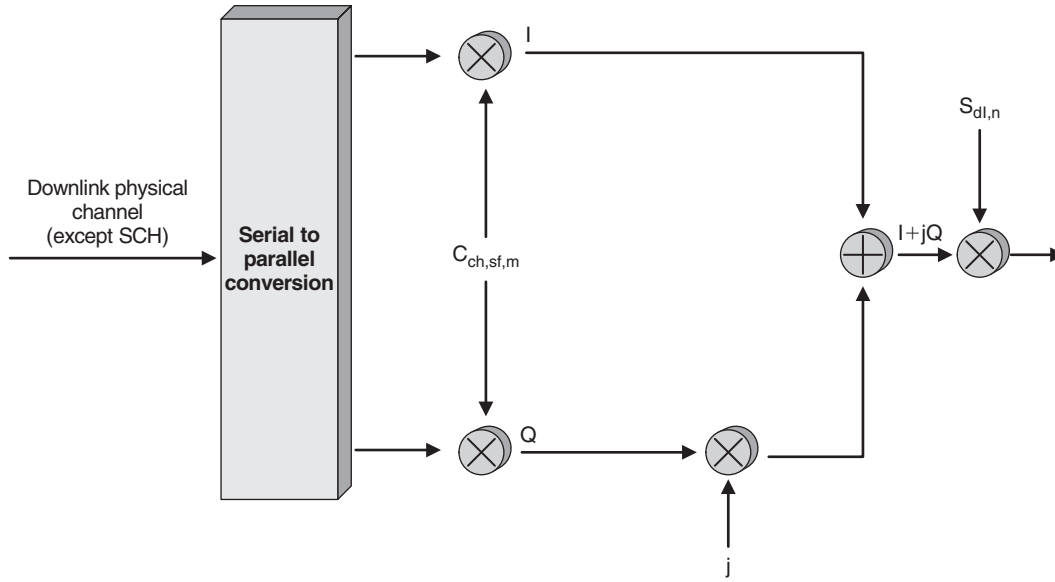

Figure 24: Downlink spreading and scrambling

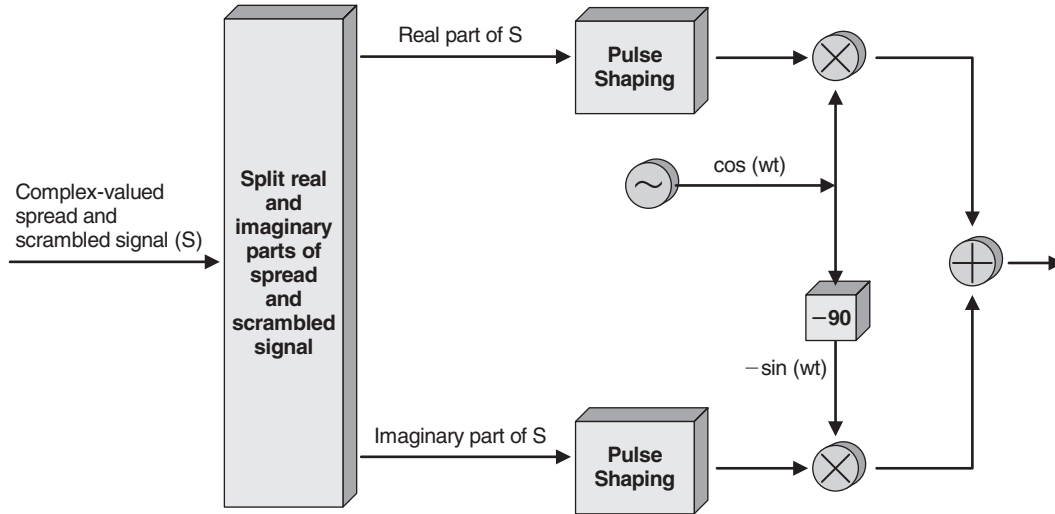

Figure 25: UTRA modulation

is $2^{18}-1$ (262,143), but only a subset of them (7,680) is used, which is further divided into primary and secondary codes in order to enhance the speed of the process.

The modulation scheme used in both uplink and downlink is quadrature phase shift keying (QPSK); Figure 25 shows the process. The stream of complex-valued chips is split into two parts: the real and imaginary bit streams. The two branches (real and imaginary) of the scrambled signal are applied to the modulator branches (I and Q).

Channel Coding and Code Allocation in UTRA

The channelization coding scheme used is called orthogonal variable spreading factor (OVSF) and is represented by the tree in Figure 26. The channel is spread by one of the spreading factors in the following set: 4, 8, 16, 32, 64, 128, and 256. The spreading factor, which affects the

bandwidth used, is chosen depending on the data rate required. In general, the smaller the factor used, the larger the data rate. For instance, if a factor of 8 is to be chosen to spread data for the DPDCH, this gives a data rate of 480 kbps ($3.84 \times 10^6/8 = 480 \times 10^3$). For instance, if multiple DPDCHs are to be transmitted, the following are the codes applied:

- $C_{ch,4,1}$ spreads DPDCH₁ and DPDCH₂
- $C_{ch,4,2}$ spreads DPDCH₃ and DPDCH₄
- $C_{ch,4,3}$ spreads DPDCH₅ and DPDCH₆

In general, codes are chosen carefully. Basically, codes of the same user should be orthogonal. Also, as in the example above, codes of adjacent channels can be similar (1 and 2, 3 and 4, or 5 and 6) but codes for two even or two odd channels cannot. This is because adjacent channels are separated by the I and Q separation.

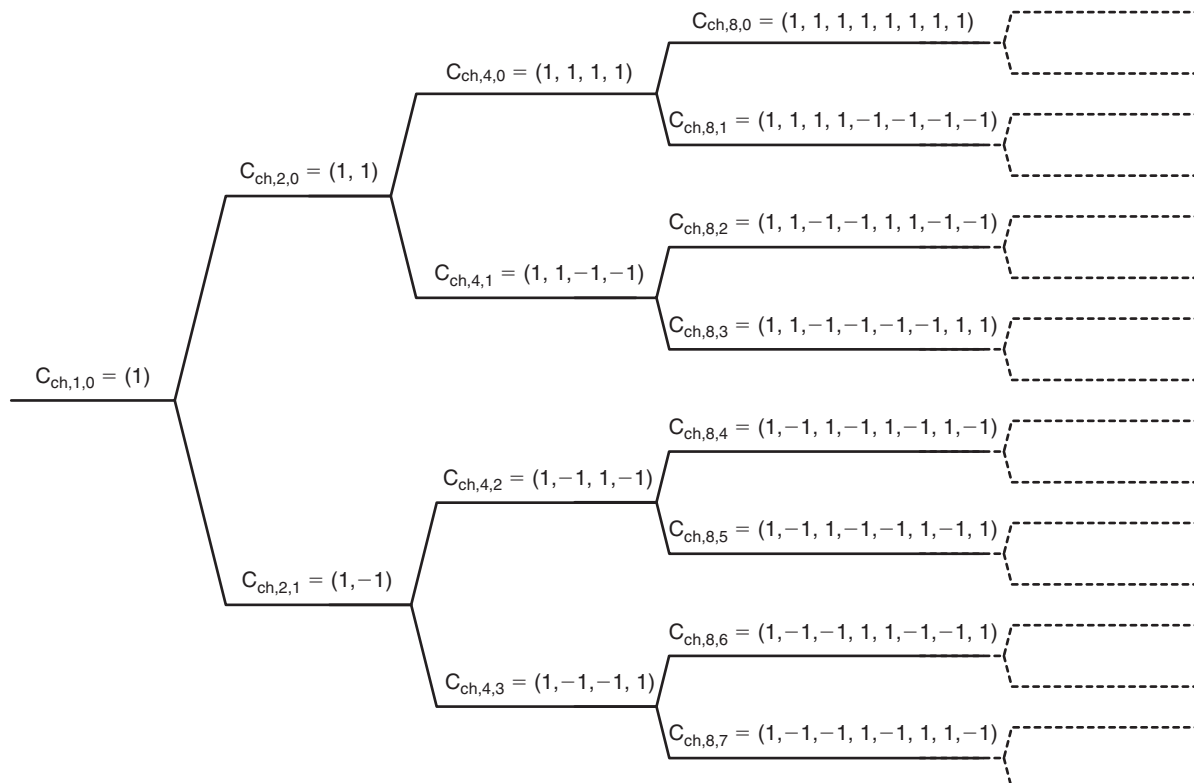

Figure 26: Spreading code tree—OVSF

Rate Matching in UTRA

Rate matching means that bits on a transport channel are repeated or punctured. Higher layers assign a rate-matching attribute for each transport channel. This attribute is semi-static and can only be changed through higher layer signaling. The rate-matching attribute is used when the number of bits to be repeated or punctured is calculated.

The number of bits on a transport channel can vary between different transmission time intervals. In the downlink, the transmission is interrupted if the number of bits is below maximum. When the number of bits between different transmission time intervals in the uplink channel is changed, bits are repeated or punctured to ensure that the total bit rate after transport channel (TrCH) multiplexing is identical to the total channel bit rate of the allocated dedicated physical channels.

If no bits are input to the rate matching for all TrCHs within a coded composite transport channel (CCTrCH), the rate matching will output no bits for all TrCHs within the CCTrCH and no uplink DPDCH will be selected in the case of uplink rate matching (3GPP 2006).

CDMA2000 LAYERS AND PHYSICAL CHANNEL STRUCTURES

cdma2000 Layering Structure

Upper-Layer Functions

Figure 27 shows the cdma2000 layering structure. In terms of each layer's services, the upper-layer functions can be summarized as follows:

- Voice services: voice telephony service, in all its flavors—mobile, PSTN, or IP telephony
- End user, data-bearing services: data services initiated by the user, including packet data, circuit data, and SMS
- Signaling: services that control the operation of the mobile

Link Layer Functions

The link layer, as shown in Figure 27, can be divided into two sublayers: MAC and LAC. Collectively, the link layer translates reliability and QoS requirements of higher layers to the physical layer. Specifically, the LAC sublayer provides point-to-point communication channels between peer upper layers as well as end-to-end reliable link layer services. The MAC layer, on the other hand, provides three important functions:

- Media access control state: controls the access of higher-layer data services to the physical layer
- Best-effort delivery: provides a best-effort level of reliability in transmission
- Multiplexing and QoS control: enforces the claimed QoS levels through prioritizing services' access

Quality of Service

The MAC sublayer has the following subdivisions:

- Physical layer independent convergence function (PLICF)
- Physical layer dependent convergence function (PLDCF)

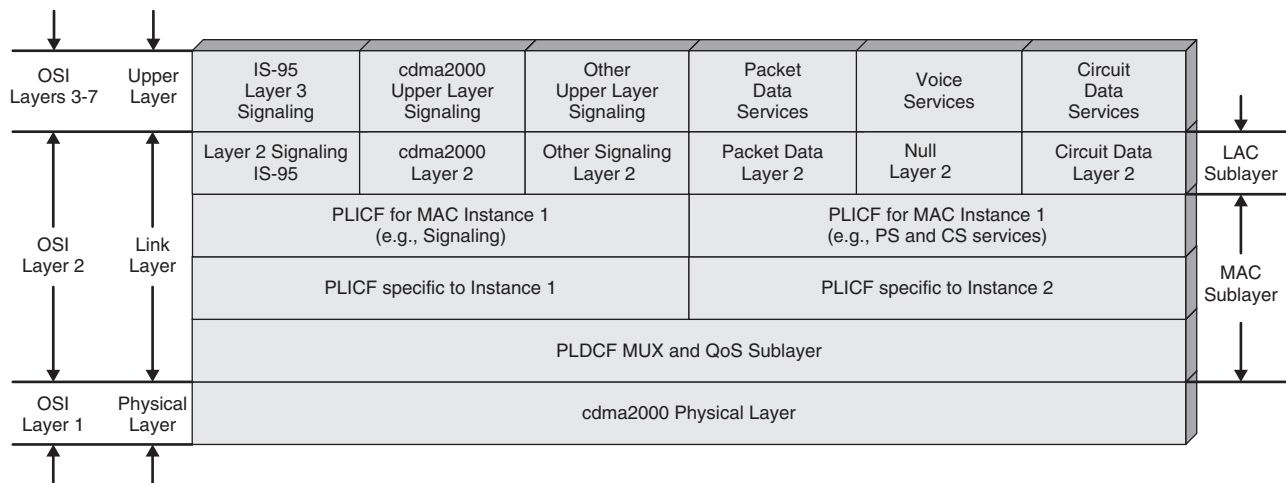

Figure 27: cdma2000 layers

- PLDCF MUX and QoS
- Instance-specific PLDCF

With this structure, the MAC sublayer provides the LAC sublayer with different QoS levels. The role of the PLICF is to provide those operations and functions that are independent of the physical layer to the MAC sublayer. Furthermore, the PLICF data service maintains state information about all of its services. The PLICF accomplishes its actual operations through the use of PLDCF functions. In other words, the PLDCF provides the interfacing between PLICF logical channels and the logical channels supported by the physical layer. PLDCF also enforces QoS levels in various ways, including the automatic retransmission request (ARQ) and the resolution of competing PLICF data services requests. Finally, the LDCF MUX and QoS sublayer coordinates the multiplexing/demultiplexing of code channels from multiple PLICF instances while ensuring requested QoS levels.

Physical Layer Functions

The physical layer mainly provides coding and modulation services for the LDCF MUX and QoS sublayers. The physical channels fall in two categories:

- Forward/reverse dedicated physical channels (F/R-DPHCH): channels used for the unicast transmission (point-to-point) from the base station to the mobile station
- Forward/reverse common physical channels (F/R-CPHCH): channels used for the broadcast or multicast transmission (point-to-multipoint) from the base station to the multiple mobile stations.

New Channels in the Physical Layer

The new channels in the physical layer of cdma2000 are shown in Table 7.

cdma2000 Reverse Link

Reverse Link Features

The key features of the reverse link are:

- Channels are primarily code-multiplexed
- Separate channels are used for different QoS and physical layer characteristics
- Transmission is continuous to avoid electromagnetic interference
- Channels are orthogonalized by Walsh functions and I/Q split so that performance is equivalent to binary phase shift keying (BPSK)
- Hybrid combination of QPSK and BPSK
- Coherent reverse link with continuous pilot
- Forward power control information is time-multiplexed with the pilot
- By restricting alternate phase changes of the complex scrambling, power peaking is reduced and side lobes are narrowed
- Independent fundamental and supplemental channels with different transmit power and frame error rate (FER) target (Garg 2001)
- Forward error correction
- Fast reverse power control
- Frame lengths

Physical Channels Structures

The various physical channels in the reverse link are listed in Table 8. R-FCH, R-SCH, and R-SCCH are known collectively as reverse traffic channels. Figure 28 shows the structure of the reverse link channel in cdma2000.

Physical Channel Spreading

The reverse link in cdma2000 uses orthogonal spreading to distinguish user channels. Code channels are associated

Table 7: New Channels in the cdma2000 Physical Layer

with a Walsh function (see Figure 32) W_n^N of length 2^N Walsh chips, where $N = 1, 2, \dots, 6$. BPSK symbols are multiplied by the Walsh function at a fixed chip rate (1.2288 Mcps).

Enhanced Access Channel

The enhanced access channel (EACH) is used for the communication from the mobile station to the base station (reverse link), to initiate communication, or to respond to a mobile-directed message. It has three modes:

- Basic access mode: The enhanced access probe contains the enhanced access channel preamble and the enhanced access data.
- Powered controlled access mode: The enhanced access probe contains the enhanced access channel preamble,

the enhanced access header, and the enhanced access data.

- Reservation access mode: The enhanced access probe contains the enhanced access channel preamble and the enhanced access header. The enhanced access data is sent on the R-CCCH upon receiving the permission from the base station.

Power Control Subchannel

The mobile station inserts a reverse power control subchannel (PCCH) on the reverse pilot channel (R-PICH) when operating on the reverse traffic channel (R-TCH) with RC3 through RC6. The mobile station supports both the inner power control loop and the outer power control loop for the forward channel power control loop.

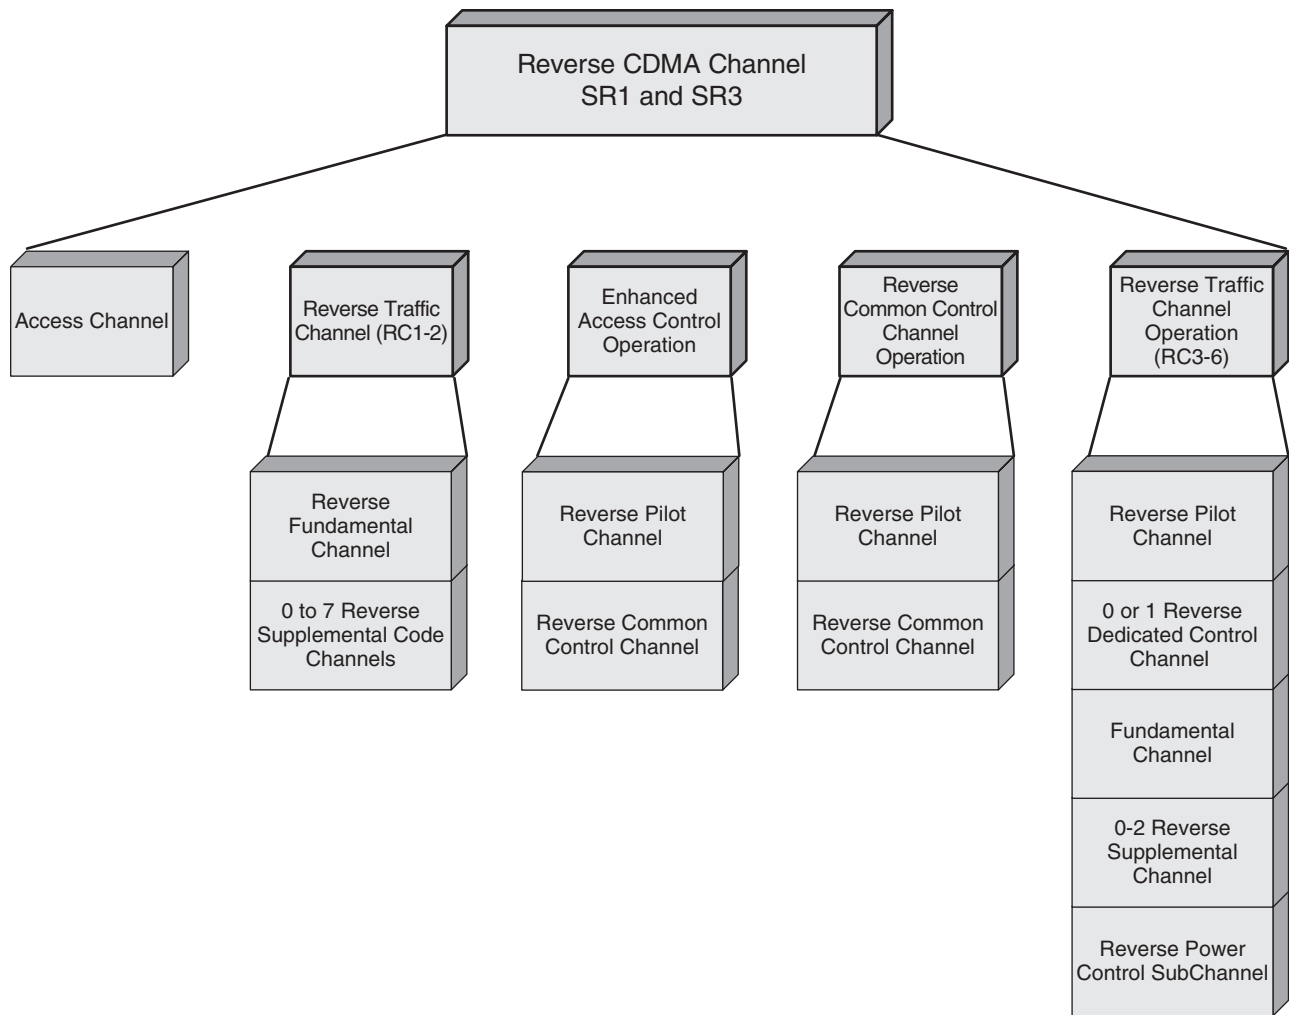

Figure 28: cdma2000 reverse link channel structure

I and Q Mapping

Figure 29 shows the I and Q mapping process that takes place after the application of the Walsh function. Coded channels are mapped to either the I or the Q branch of the complex multiplier that follows, depending on the type of channel being mapped. The mapping is predetermined, and the important thing is that channels in the same branch are chosen to be orthogonal, because they will be added together in the branch (for both I and Q branches).

cdma2000 Forward Link

Forward Link Features

As Figure 30 shows, the forward link can support multiples of the 1.2288 Mcps. This gives what is called the cdma2000 multicarrier NX, when the chip rate is $N \times 1.2288$ Mcps (where $N = 1, 3, 6, 9, 12$). The simplest case is when $N = 1$, which is the case in IS-95B but with QPSK and fast closed-loop power control. On the other hand, for $N > 1$, modulation symbols are multiplexed on N separate 1.25 MHz carriers, where each carrier is spread at a rate of 1.2288 Mcps.

Physical Channels Structures

The various physical channels in the forward link are shown in Table 9. F-FCH, F-SCH, and F-SCCH are known

collectively as forward traffic channels. Figure 31 shows the structure of the forward link channel in cdma2000.

Physical Channel Spreading

The forward link in cdma2000 also uses orthogonal spreading to distinguish user channels. Code channels are associated with a Walsh function (see Figure 32) W_n^N of length 2^N Walsh chips, where $N = 1, 2, \dots, 7$. The I and Q values of the complex modulation are multiplied by the Walsh function at a fixed chip rate (1.2288 Mcps).

Modulation and Spreading for Single- and Multi-Carrier Systems

The common modulator used with the forward link of cdma2000 is QPSK. The sole purpose of using the QPSK is to increase bandwidth.

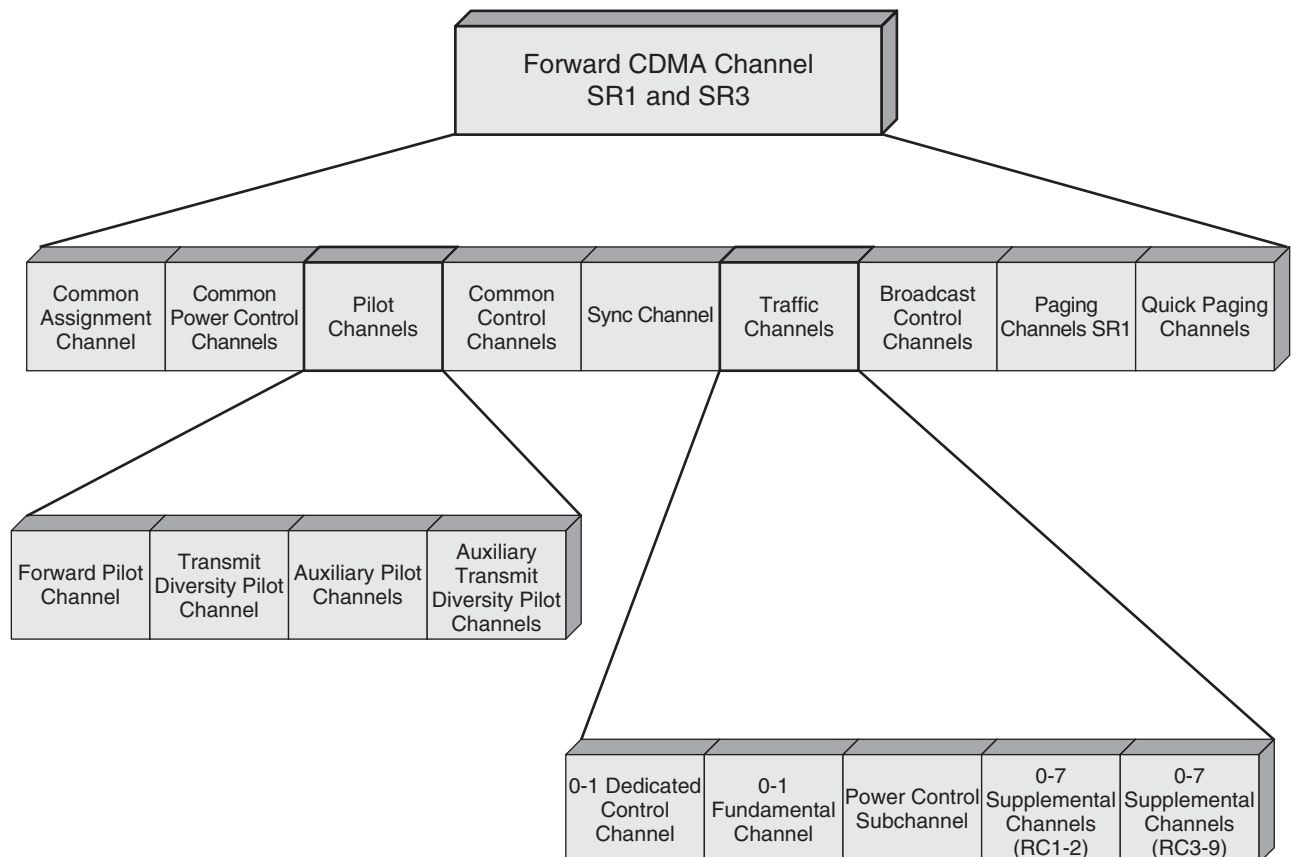

Channel Coding and Interleaving in cdma2000

Error Correction in cdma2000

cdma2000 incorporates a forward error correction (FEC) mechanism that reduces the required signal-to-interference-noise ratio (SINR) for the required FER performance. There are two types of FEC: convolutional

**Figure 31:** cdma2000 forward link channel structure

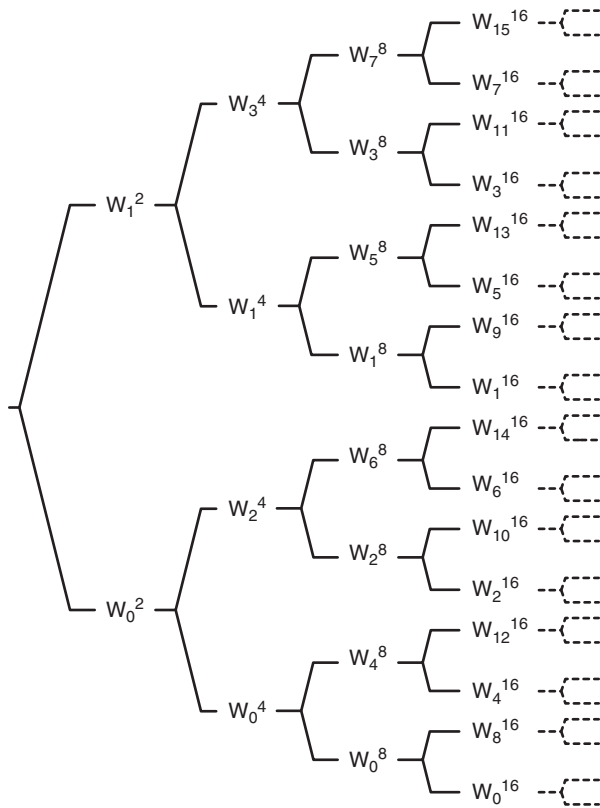

Figure 32: Walsh code

and turbo coding. The convolutional coding is suitable for short payloads, and the turbo coding is more effective in longer payloads. In general, the coding gain (gain calculated by the enhancement on the SINR in coded systems from systems absent coding) for turbo coding is proportional to the turbo interleaver size. Accordingly, turbo coding performs better with higher payloads (huge data services); otherwise, convolutional coding performs better.

Code Puncturing

After coding and before modulation, the rate of the coded symbols should be matched to one of the allowable data rates. This rate matching is similar to that in UTRA and should take place because of the differences in data rates and frame sizes of traffic channels. Repetition occurs when traffic channel-coded symbols are transmitted with a rate less than or equal to the full rate. These patterns are repeated as appropriate. But when traffic channel-coded symbols are transmitted with a rate that is a multiple of the full rate, the symbol pattern is punctured. The process of puncturing eliminates specific coded symbols and maintains others depending on the radio configuration (RC).

Turbo Coding

Turbo coding was originally presented in Berrou, Glavieux, and Thitimajshima (1993). Its performance is superior to other coding techniques, mainly because its bit

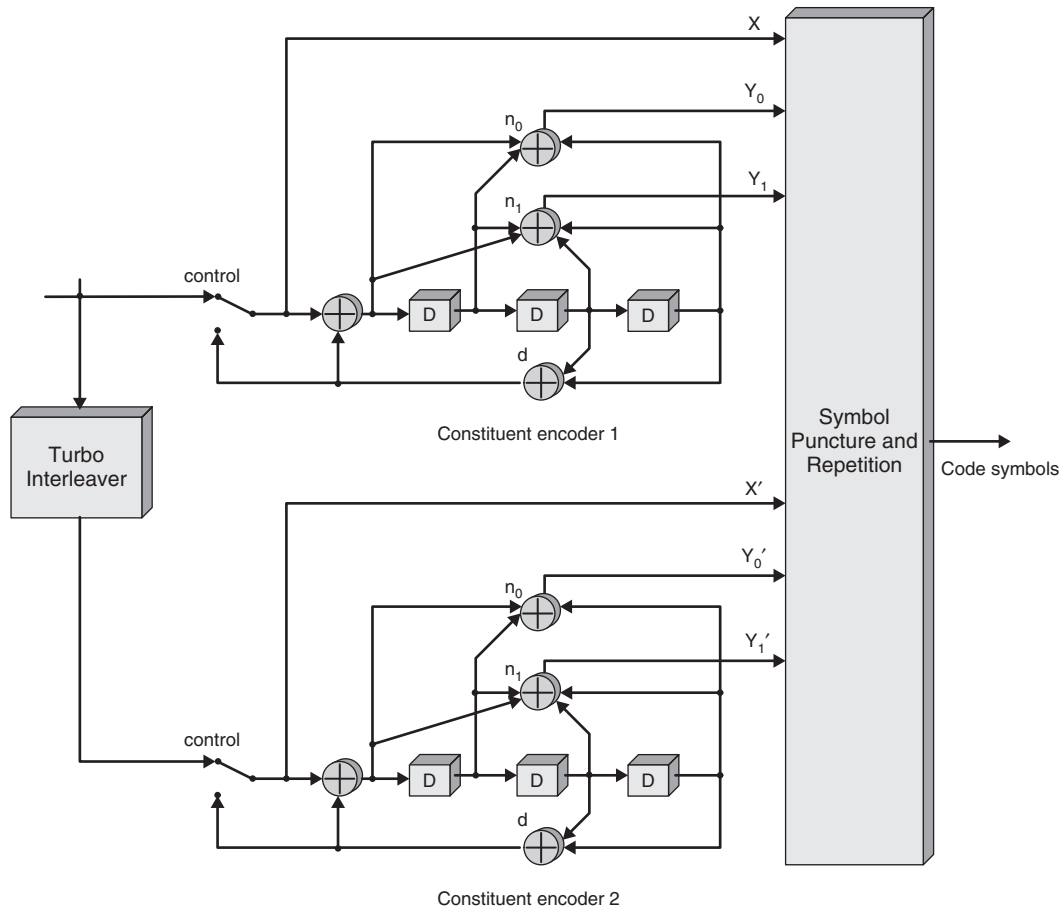

Figure 33: cdma2000 turbo coding

error rate (BER) is within a decibel or so from the Shannon capacity limit, especially when coupled with large interleavers (Vanghi, Damnjanovic, and Vojcic 2004). As shown in Figure 33, the turbo code encoder for cdma2000 is made up of two recursive convolutional encoders of length 4. The D boxes are registers that form a shift register. In convolutional coding, output bits depend on the current input bit and previous input bits. If, during each clock interval, two output bits are generated for a single input bit, we say the code rate is $\frac{1}{2}$. Similarly, if three output bits are generated, the code rate is $\frac{1}{3}$, and so on. Inherent in the turbo coder is the interleaved bit sequence, which highly affects the FER performance.

Forward Link Interleaving

Channel interleaving takes place after the FEC process on the transmitting side and before the FEC on the receiving side. The whole purpose is to immunize the transmitted data against fading. There are two types of interleavers: the bit-reversal-order interleaver and the forward-backward bit-reversal interleaver. Both techniques tend to arrange the input bit stream into a matrix while writing in columns and reading in rows.

CONCLUSION

The IMT-2000 specification was illustrated throughout the whole chapter, and the various 3G wireless technologies were discussed with broader interest in W-CDMA and cdma2000—those being the major market trends. In this chapter, network architecture and service characteristics were the two mainly tackled issues of mobile wireless systems. This fact makes the text easy to follow; it allows beginners to get a broad introductory view of the subject yet proves informative for specialists interested in enriching their knowledge.

GLOSSARY

Analog: A method of modulating radio signals so that they can transmit voice or data information.

Antenna: A physical device that enhances or facilitates the transmission and reception of radio signals.

Authentication: A feature that decreases fraud by creating a unique set of variables to identify the phone's identity.

Bandwidth: The range of frequencies a signal can be transmitted without distortion over a transmission medium.

Base Station: A fixed station in a mobile radio system used for radio communications with mobile stations. Base stations are located at the center or on the edge of a coverage region, and consist of radio channels and transmitter and receiver antennas mounted on a tower.

Broadband: A communications medium that uses a wide-bandwidth channel for transmitting large amounts of voice, data, or video information.

Carrier: A company that provides wireless telecommunications services.

CDMA (code division multiple access): The transmission of messages from a large number of transmitters

over a single channel by assigning each transmitter a pseudo-random noise code (typically more than 2,000 symbols long for each bit of information) so that the codes are mathematically independent of one another.

Cell: The geographic area in which an individual cell station handles a particular call.

Cellular: The most familiar type of wireless communication. Originally called "cellular" because each service area was divided into cells.

Coding: The altering of the characteristics of a signal to make the signal more suitable for an intended application, such as optimizing the signal for transmission, improving transmission quality and fidelity, modifying the signal spectrum, increasing the information content, providing error detection and/or correction, and providing data security.

Digital: An encoding method using the binary code of 1s and 0s.

Downlink: The transmission link from the fixed part (base station) to the portable part (mobile station).

Duplex: The ability to receive and send a signal at the same time.

Encryption: A method of encoding plain text for security purposes.

FCC (Federal Communications Commission): A U.S. governing agency that regulates the communications industry.

FDMA (frequency division multiple access): The technology used in the analog cellular telephone network that divides the spectrum into thirty channels.

Handoff: Transferring a call from one site to another without losing the connection.

ISO (International Standards Organization): The body responsible for setting world technical standards. It is based in Geneva, Switzerland.

Landline: Traditionally wired telephone service.

MMS (multimedia messaging service): Similar to SMS, but, in addition to plain text, MMS messages may include multimedia elements such as pictures, video, and audio. These multimedia elements are included in the message, not as attachments (as with e-mail).

Modulation: The addition of information (or the signal) to an electronic or optical signal carrier. Modulation can be applied to direct current (mainly by turning it on and off), to alternating current, and to optical signals.

Paging: A wireless device feature that allows one to receive an alphanumeric message.

PCS (personal communication system): A wireless communications technology that operates at 1900 MHz.

PSTN (public switched telephone network): A formal name for the worldwide telephone network.

Roaming: Using your wireless phone in an area outside its home coverage area. There is usually an additional charge for roaming.

RF (radio frequency): A radio signal.

SMS (short messaging service): A PCS phone feature that permits users to receive and transmit short text messages.

Spectrum: The entire range of electromagnetic frequencies.

TDMA (time division multiple access): A satellite and cellular phone technology that interleaves multiple

digital signals onto a single high-speed channel. For cellular, TDMA triples the capacity of the original analog method (FDMA). It divides each channel into three subchannels, providing service to three users instead of one. The GSM cellular system is also based on TDMA, but GSM defines the entire network, not just the air interface.

Uplink: The transmission link from the portable part (mobile station) to the fixed part (base station).

Wireless CDMA Channels	764	References	767

CDMA CONCEPT

Code Division Multiple Access (CDMA) is based on a technology known as spread spectrum. While CDMA focuses on the multiple access, spread spectrum has a lot more to offer. Therefore we start by giving a short historical background on the invention and principles of spread spectrum systems.

Historical Background

The story of the invention of spread spectrum technology is one of the most interesting ones in the world of communication engineering. Spread spectrum, particularly the frequency-hopping technique, was invented by the actress Hedy Lamarr, who was born in Austria in 1914 under the name Hedwig Eva Maria Kiesler. In Europe she started her career as an actress and married the multi-millionaire Friedrich Mandl, who was in the defence manufacturing business. During World War II, she attended many of her husband's business meetings and learned about the problems of remote controlled torpedoes used by the marines. Those torpedoes were controlled wirelessly by the English and Americans to direct them against German ships. Because the accuracy of the torpedo was not high enough, manual fine tuning was needed. For the wireless control, a narrow band signal was used. Once the Germans discovered the control signal transmitted by a narrow-band carrier, they could easily jam that signal to avoid the torpedo hitting its target. Hedy Lamarr came up with the idea of using multiple frequencies. The communication should take place on one frequency at a time and then jump to another channel (e.g., frequency) fast enough so as not to give the enemy enough time to tune in the new frequency to jam it. Certainly, the change in frequency should not be predictable to the enemy. Lamarr's problem was that the change in frequency (or frequency hopping pattern) had to be synchronized between the sender on the boat and the receiver in the torpedo. After some time, Lamarr's friend George Antheil came up with a solution. Antheil had a bar in Paris with automatic pianos that were played by a piano roll. The roll had perforations in it which told the piano which keys had to be played and for how long. Eighty-eight perforations were possible in parallel (one perforation for each key on the piano).

A so-called tracker bar was used to sense the holes and give the commands to the piano. The same mechanism was envisioned for the torpedo to keep synchronization. In 1942 Lamarr and Antheil filed U.S. patent number 2,292,387 entitled *Secret Communication System* (see Figure 1). After the filing process, they offered the invention to the American military. The application of the described invention was questioned with the reasoning that *torpedoes are not large enough to place a piano in them*. In 1962, spread spectrum was used by the militaries for the first time in the Cuba crisis. Hedy Lamarr died in 2000.

Basic Principles of Spread Spectrum

Spread-spectrum techniques gained popularity through the needs of military communications. In contrast to narrow-band communication, spread-spectrum techniques were more resistant to hostile jammers and more difficult to intercept, two fundamental conditions for tactical communications. For a communication system to be considered a spread-spectrum system, the following criteria have to be satisfied, as given in Cooper and McGillem (1986):

- The bandwidth of the transmitted spread signal has to be greater than the information bandwidth. Note that this criterion is also satisfied by frequency modulation, pulse code modulation, and delta modulation.
- The spread signal is composed of the information signal and the spreading sequence. The spreading sequence has to be independent (in the statistical sense) from the information.

The ratio of spreading bandwidth B_s to information bandwidth B_i is denoted as the processing gain $G_{\text{Spreading}} = B_s/B_i$ of a spread-spectrum system.

The processing gain does not combat white noise with frequency modulation and pulse code modulation, because the spread signal is independent of the information signal. However, spread-spectrum signals offer the following advantages for a wireless communication system:

- Spread-spectrum modulation is capable of dealing with the multi-path signals resulting from the radio channel. These signals can be considered as interference and therefore be suppressed, or the multi-path signals can be effectively exploited by collecting them, as in a rake receiver. In the section titled "Rake Receiver" we will discuss enhanced techniques developed to suppress multi-path interference even further. The multi-path interference rejection gain depends on the used spread-spectrum scheme and modulation methods.
- The receiver of a spread-spectrum system is able to distinguish between different transmitted signals using the spreading sequence. Spreading sequence design is very important for multiple access capability. The spreading sequence is actually the identification for a transmitter-receiver pair.
- Other advantages such as low probability of interception, privacy, and anti-jam capability are more relevant for military needs.

Different spreading techniques are possible. Figure 2 provides a classification of spread spectrum techniques. The diagram shows techniques such as **D**irect **S**equences (**DS**), **F**requency **H**opping (**FH**), and **T**ime **H**opping (**TH**), along with their sub-classifications. These techniques can be combined to combat their disadvantages and combine their benefits. Such systems are referred to as hybrid spread-spectrum systems. These systems consist of combinations of two or more basic spread-spectrum systems. There are four possible hybrid systems, namely DS/FH, DS/TH, FH/TH, and DS/FH/TH, as shown in Figure 2.

The following section gives a short introduction to the different spreading techniques and discusses their benefits.

Direct Sequence

In a **D**irect **S**equences **S**pread **S**pectrum (**DSSS**) transmitter, the information signal is directly modulated by a spreading sequence. The spreading sequence consists of a number of spreading chips with time duration τ_{chip} . The information signal consists of a number of information bits with time duration τ_{bit} . Spreading is achieved if multiple chips represent one bit.

In Figure 3, a DSSS transmitter and receiver are depicted. At the sender side the information signal $i(t)$, with data rate R_i and bandwidth B_i , is spread by a spreading sequence $c(t)$. The spreading sequence has the code symbol rate R_c , also called the chip rate. If τ_{bit} is a multiple of τ_{chip} the processing gain G_{DS} can be easily calculated by:

$$G_{\text{DS}} = \frac{\tau_{\text{bit}}}{\tau_{\text{chip}}} \quad (1)$$

Figure 4 shows a possible DSSS transmission and reception process. It can be seen how the original information signal $i(t)$ is spread before the transmission over the wireless link and how it will be despread at the receiver side. Furthermore, the influence of the jammer is also considered. If the data rate R_i is very small in comparison to the chip rate R_c , then the spread signal $s(t) = i(t) \cdot c(t)$ will have approximately the bandwidth of the spreading signal ($B_c \approx B_s$). At the receiver end the received signal $r(t)$ will be multiplied once again with the same spreading sequence $c(t)$, which results in a despreading of the original signal $i(t)$, if the autocorrelation $\varphi_{cc}^E(\tau)$ is nearly zero for all $\tau \neq 0$. After the despreading, the signal will be filtered with bandwidth W_i to remove high frequencies.

The generation of DSSS signals can be achieved by a simple multiplication of the information and spreading sequences. Figure 5 shows the principle used for

Figure 2: Classification of different spread spectrum systems

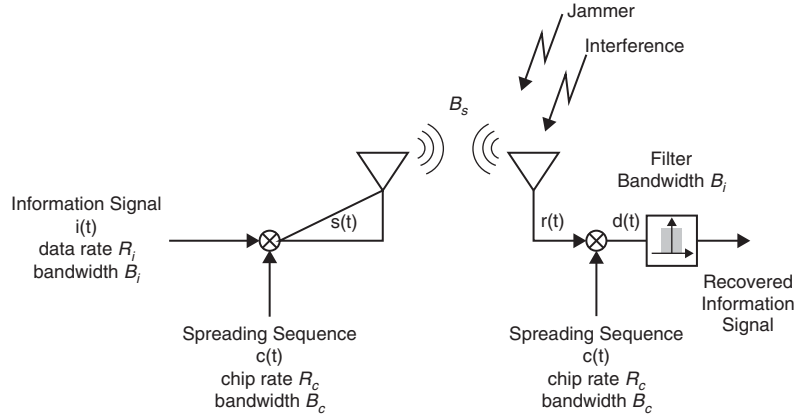

Figure 3: System model for spread spectrum transmission

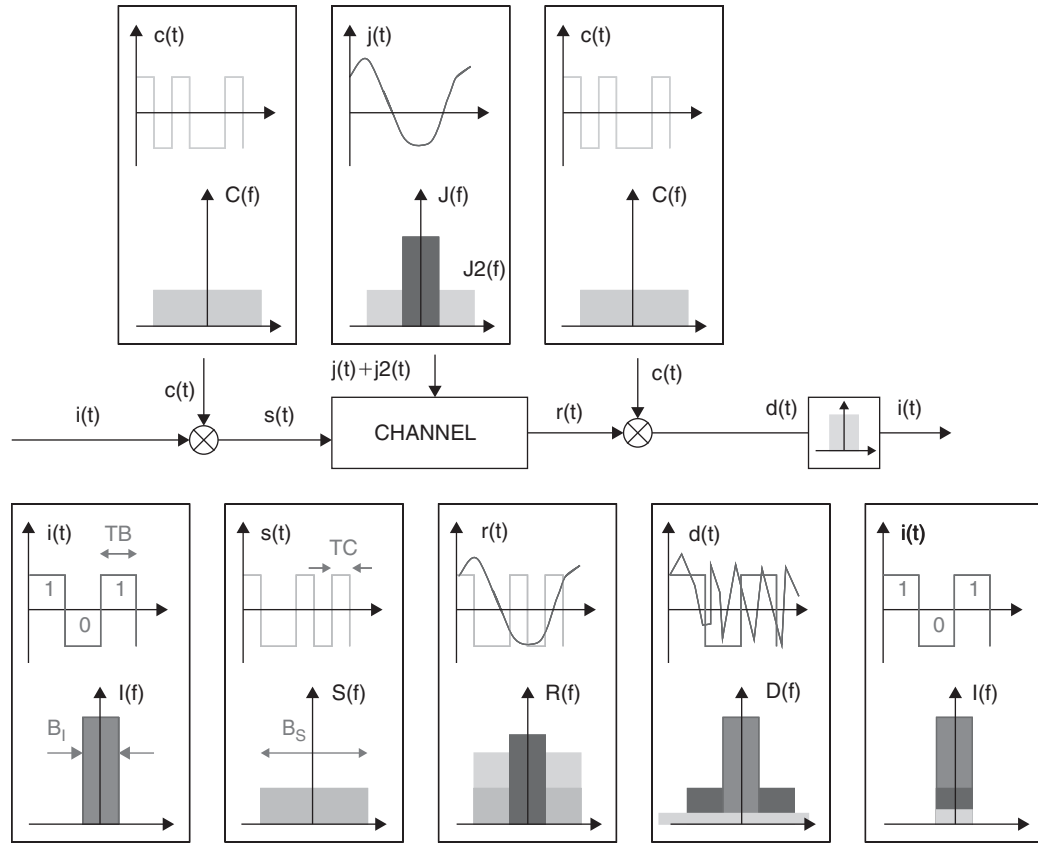

Figure 4: Transmission and reception process in a direct sequence spread-spectrum system

generating a DSSS signal for $G_{DS} = 10$. A key feature of DSSS is that multiple access capability can be achieved without synchronization between different transmitters. Multi-path interference is combated if delayed signals differ by only one chip duration. In this case all delay signals are treated as interference. On the other side the transmitter-receiver pair has to be fully chip-synchronized, as will be explained later in more detail. As explained in the section titled "Power Control Mechanism," the near-far effect has to be taken under consideration, because DSSS systems use the full bandwidth and therefore a

transmitter closer to the receiver will constantly interfere and eventually destroy signals from transmitters that are far away.

Frequency Hopping

Frequency Hopping Spread Spectrum (FHSS) systems periodically change the carrier frequency of the modulated information signal in a random fashion. During a time interval τ_{hop} the frequency is constant. Afterwards both the sender and receiver *hop* to another frequency. The whole bandwidth B_s is divided into frequency slices

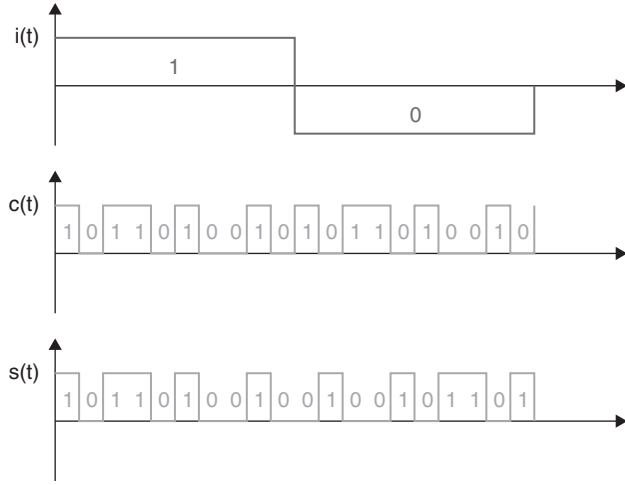

Figure 5: Direct sequence spread-spectrum signal generation, $G_{DS} = 10$

of B_s . The set of available frequencies is called a hop-set with N frequency slices. FHSS systems differ radically from DSSS systems in terms of frequency occupancy. While DSSS systems occupy the whole bandwidth all the time, FHSS systems use only one frequency slice at any point in time. FHSS systems are usually classified into *slow* and *fast* frequency hoppers, as depicted in Figure 2. If one information bit is transmitted over several frequency slices ($\tau_{hop} \leq \tau_{bit}$) the frequency hopper is referred to as *fast*. Otherwise if several bits are transmitted over one frequency slice, it is referred to as a *slow* hopper. The relation of hop duration τ_{hop} to information bit duration τ_{bit} depends upon the number of hops per information bits. If τ_{bit} is an integer multiple of τ_{hop} , then we denote $\tau_{bit} = k \cdot \tau_{hop}$. This leads to the processing gain G_{FH} (see Cooper and McGillem 1986).

$$G_{FH} = \frac{B_s}{B_i} = N \cdot k \cdot B_s \cdot \tau_{hop} \quad (2)$$

The advantage of FHSS systems in contrast to DSSS systems is the less strict synchronization requirement. FHSS allows synchronization errors of the size of τ_{hop} , DSSS only of the size of τ_{chip} (Prasad 1996).

Time Hopper

Within a **Time Hopping Spread Spectrum (THSS)**, system the time axis is divided into frames of the duration τ_{frame} . As depicted in Figure 6, each frame is divided again into N slots with time duration τ_{slot} .

A single wireless terminal (WT) will only use one slot out of k possible slots within one frame. Within this slot, the WT sends with a k times higher data rate, in contrast to the situations in which the WT would transmit within the whole frame. Interference among simultaneous wireless terminals can be minimized if coordination between terminals can be achieved. This also avoids the near-far effect. In the absence of coordination, situations occur in which more than one terminal uses a time slot. The receiver will not be able to detect either of the signals correctly. Both terminals *collide* on the wireless link. For such, cases error correction schemes are required. Time hoppers have nearly the same acquisition time as that of discrete-sequence systems, but their implementation is much simpler than that of a frequency-hopper.

Hybrid Systems

Hybrid spread spectrum systems consist of combinations of two or more basic SS systems. Therefore, there are four possible hybrid systems by combining such systems, namely DS/FH, DS/TH, FH/TH, and DS/FH/TH. The combination of different SS schemes leads to increased complexity of the transmitter and receiver, but also offers a combination of their advantages. For instance, if DSSS and FHSS schemes are combined, the hybrid SS system offers the multi-path interference rejection of the DSSS system and the immunity of the FHSS system. Table 1 briefly lists the advantages and disadvantages of different SS schemes in terms of multiple access capability, multi-path interference rejection, synchronization, and hardware complexity.

CDMA Basics

Provision of multiple access capability is indispensable in wireless communication systems, and this can be carried out in different ways. The classical approach is **Frequency Division Multiple Access (FDMA)**, where users are separated in the frequency domain. A more recent technique is **Time Division Multiple Access (TDMA)**, where users separation takes place in the time domain. Basically, FDMA and TDMA assign particular frequency or time slices to different wireless terminals. When all slices are

Figure 6: Time axis for a THSS system

Table 1: Comparison of Different Spread-Spectrum Techniques with Their Advantages and Disadvantages

SS Scheme	Advantages	Disadvantages
Direct-Sequence	<ul style="list-style-type: none"> • Best behavior for multi-path-rejection (Cooper and McGillem 1986) • Best anti-jam rejection (Cooper and McGillem 1986, Ploydoros 1994) • Best interference rejection (Cooper and McGillem 1986, Ploydoros 1994) • No synchronization among terminals (Prasad 1996, Ojanpera and Prasad 1998) • Simple implementation (Prasad 1996, Ojanpera and Prasad 1998) • Most difficult to detect (Cooper and McGillem 1986, Ploydoros 1994) 	<ul style="list-style-type: none"> • Near-far problem (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Rappaport 2001) • Require coherent bandwidth (Cooper and McGillem 1986) • Long acquisition time (Cooper and McGillem 1986, Ploydoros 1994) • Synchronization of code signal within fraction of chip time (Prasad 1996, Ojanpera and Prasad 1998)
Frequency-Hopping	<ul style="list-style-type: none"> • Great amount of spreading (Cooper and McGillem 1986, Ploydoros 1994) • No need for coherent bandwidth (Cooper and McGillem 1986, Prasad 1996, and Ploydoros 1994) • Short acquisition time (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) • Inherent security (Rappaport 2001) • Less affected by the near-far effect (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) 	<ul style="list-style-type: none"> • Complex hardware (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) • Error correction is needed (Cooper and McGillem 1986, Ploydoros 1994)
Time-Hopping	<ul style="list-style-type: none"> • High bandwidth efficiency (Cooper and McGillem 1986, Ploydoros 1994) • Less complex hardware (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) • Less affected by the near-far effect (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) 	<ul style="list-style-type: none"> • Error correction is needed (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994) • Long acquisition time (Cooper and McGillem 1986, Prasad 1996, Ojanpera and Prasad 1998, Ploydoros 1994)

occupied in the system, no additional wireless terminal can be accommodated. Multiple access capability is also provided by **Code Division Multiple Access (CDMA)**. The most common techniques of CDMA are frequency-hopped CDMA or direct-sequence CDMA. CDMA allows multiple users to simultaneously use a common channel for transmission of information (Proakis 1995). A CDMA transmitter will *code* its information signal with a code or spreading sequence particularly allocated for that user. Afterwards, the transmitter sends the coded signal to the receiver. Using the same code sequence as the transmitter, the receiver is able to decode the received signal. Also, in case the receiver receives more than one coded signal, it will be able to decode the information from the desired transmitter, if the code sequences satisfy certain cross-correlation and auto-correlation requirements (see section titled “Spreading Sequences”). The bandwidth of the coded signal is much larger than the information bandwidth. One may say that the information signal was *spread*, where spread refers to the broadening of the

signal spectrum in the frequency domain. The coding process is therefore also called a spread-spectrum modulation, while the coded signal is called a spread-spectrum signal. The spreading of the information signal gives the CDMA its multiple access capability. Figures 7, 8, and 9 show the underlying principles by which subscribers can be separated in the frequency, time, or code domain, respectively.

A key-feature of CDMA systems using **Pseudo-Noise (PN)** sequences is that they can tolerate *overload*, in terms of number of simultaneous supported users. Indeed, in contrast with FDMA and TDMA systems where system capacity is fixed, CDMA systems are characterized by soft capacity, a concept used to denote the fact that capacity is not a fixed figure but it actually can be traded with system performance. For instance, if we can tolerate a certain degradation in the performance of the connected wireless terminals of a given cell, we can further accommodate more users. Thus CDMA systems using PN sequences do not have any sharply defined system

Figure 7: FDMA

Figure 8: TDMA different multiple access techniques

Figure 9: CDMA

capacity, like TDMA or FDMA systems. But for CDMA systems using PN sequences the **Bit Error Probability (BEP)** increases with the number of active terminals. To illuminate this property, we take a frequency hopping system as an example. In Figure 10 the transmission process of two wireless terminals is given. Each terminal, following the principle of frequency hopping, *hops* to another frequency slice at the beginning of a new slot. Under certain conditions depending on the hopping strategy, both terminals might use the same frequency slice. It is obvious that in the same way as the number of wireless terminals within one cell increase, the number of collisions increase as well. In general, for a spread-spectrum based system supporting access of multiple users, having more users means increasing the so-called Multiple Access Interference (MAI) and hence degrading system performance. Similarly, in a CDMA system, the more users, the higher the multiple access interference and hence the worse the performance. This is basically caused by the non-ideal cross-correlation functions (e.g., non-zero values) of the used spreading sequences which result in added interference.

The following two sections provide a short introduction to CDMA key features. The first of these two, entitled “Rake Receiver,” introduces that topic. The section titled “Power Control Mechanism” gives a more detailed view of the power control entity. As already mentioned above, the design of spreading sequences plays a major role for a CDMA system. Therefore we introduce two different families of spreading sequences in the section with that title. Later, in the section titled “Classification of Enhanced CDMA Systems” we classify the different CDMA systems.

Rake Receiver

Multi-path degrades the system performance. CDMA receivers resolve multi-path interference if signals arrive more than one chip apart from each other. The direct LoS (Line of Sight) signal is typically the strongest one. For this strongest signal, the other multi-path signals are regarded as interference and therefore they can be

Figure 10: FHSS multiple access interference

Figure 11: Rake receiver structure with three fingers and multi-path channel

suppressed with the processing gain. However, a better receiver performance is achieved by exploiting the concept of rake receivers, which aim to collect as much as possible of the received signal replicas. The example depicted in Figure 11 illustrates the basic principle of a rake receiver. After spreading and modulation of the information signal on the transmitter side the signal suffers from the multi-path channel. Different delay entities (τ_i , $i = 1, 2, 3$) and attenuation factors (a_i , $i = 1, 2, 3$) in Figure 11 model obstacles at different distances and with different propagation properties. The multi-path signal (coming from different propagation paths) is demodulated and passed to the rake receiver. The ideal rake receiver contains a receiver *finger* for each multi-path component. In practice the number of fingers is limited by the receiver's hardware complexity or costs. For instance, in a typical case only the strongest signals with a delay of less than τ_{\max} are taken into account. In each finger, the signals are despread and time aligned with one of the multi-path channels. After the despreading process the signals are weighted and combined. The weight of a signal corresponds in the best case to its attenuation factor. Roughly speaking, the rake receiver can be seen as the inverse of the multi-path channel. If the conditions on the multi-path channel change, the parameters of the rake receiver have to be adapted. In Barretto and Fettweis (2000), the performance gain achieved with rake receivers in DS-CDMA systems is shown. Recently, rake transmitters (also called Pre-rake, while the rake receiver is also called Post-rake) have been proposed. If the multi-path channel is known at the transmitter, a rake transmitter produces weighted signals such that there will be only one signal at the receiver. Barreto and Fettweis (2000) have shown that a substantial performance improvement can be achieved by applying Pre- and Post-rakes. Note that in order to apply the Pre-rake concept, the transmitter needs to know the channel state information. As always, in these cases the trade off between performance improvements and hardware/system complexity needs to be considered.

Power Control Mechanism

In a DS-CDMA system, all transmitters use the same bandwidth at the same time to send their information to the receiver. If we consider multiple transmitters connected to one receiver, the signals are received with different power levels, because wireless terminals are located at different distances from the base station. In practice, the signal

strength can differ in the range of 100dB (Shapira 1999). Due to the attenuation effect, the (received) signals from transmitters closer to the receiver have higher power levels than those from transmitters that are far away. This phenomenon is called the *near-far effect*. The near-far effect plays an essential role if multi-user interference is considered. For free-space propagation, the received power falls off proportional to the square of the distance from the wireless terminal to the base station. In addition to the near-far effect, the signal strength differs dramatically due to the changing propagation conditions (moving obstacles, traffic characteristics, hand over). To overcome the changing signal strength, power control entities are implemented in the transmitters. These entities are called **Transmitter Power Control (TPC)**. The TPC adjusts the transmission power P_{tx} at the sender-side to ensure that all signals arrive at the receiver with the same power level P_{rx} . Without such a functionality, weak signals are being masked by strong signals, making it difficult or impossible to detect the former.

For cellular CDMA mobile communications systems, the TPC plays a major role, particularly in the up-link. TPC for the down-link are only implemented to adjust a required **Signal to Interference plus Noise Ratio (SINR)**. Recall that the CDMA capacity is interference limited. Thus, the lower the power level of one terminal, the higher is the number of supported terminals. The TPC for the down-link is only implemented to adjust a required SINR. In contrast to the up-link, the conditions on the down-link change more slowly. Most TPCs consist of two types of power control, namely open-loop and closed-loop. Some wireless CDMA communication systems also have an outer loop power control, such as IS-95 (EIA/TIA 1997). The open-loop power control measures the SINR of the incoming signals and adjusts the transmission power to meet the desired SINR. Unfortunately, the conditions for up-link and down-link can differ dramatically, e.g., due to the use of frequency division multiplexing, and therefore the open-loop power control provides only a first estimation for the TPC. The closed-loop power control measures the signal power at the receiver and controls the transmitter's power. IS-95 receivers send only one bit of information to change the transmitting power in the range of 1dB/1:25ms at the transmitter side. The outer loop power control gets information about the **Packet Error Probability (PEP)** and compares it with the required PEP. In case of deviations, the transmitter power is adjusted. A block diagram of the power control loops of IS-95 is shown in Figure 12.

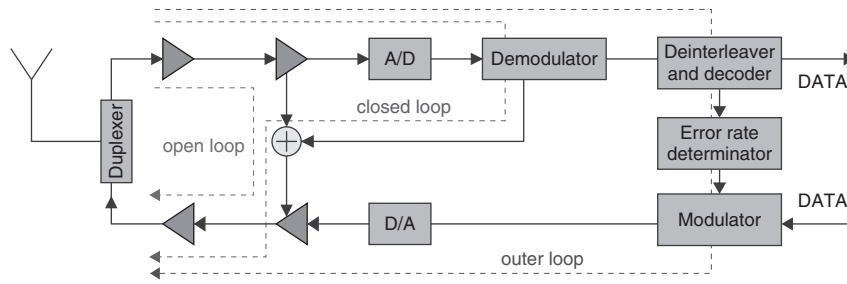

Figure 12: Power control loops for IS-95

In Jansen and Prasad (1995) it is shown that the probability density function (*pdf*) of the received power depends on the TPC algorithm, speed of the Adaptive Power Control (*APC*) system, dynamical range of the transmitter, spatial distribution of the wireless terminals, and propagation statistics. In Jansen, Prasad and Kegal (1993), it is shown that the *pdf*-function can be assumed to be log normal. The *pdf* was given as

$$f(P_{rv}) = \frac{1}{\sqrt{2\pi} \sigma P_{rv}} \cdot \exp\left[-\frac{\ln^2(P_{rv})}{2\sigma^2}\right] \quad (3)$$

where σ is the imperfection in the TPC entity. In Jansen and Prasad 1995 it is shown that the performance degradation of a DS CDMA system with $\sigma = 1$ dB was about 60%. Therefore the system performance of a CDMA systems depends particularly on the system parameter σ . The smaller σ the better the performance. Notice that not only the variance of the used energy within one cell has to be taken into consideration, but also the inter-cell interference plays an important role in CDMA systems. In Figure 13 the interference produced/received by the center cell for/from neighboring cells is given. In Gibson (1996) it is claimed that each cell in the first tier (see Figure 13) contributes/receives about 6% of the interference. Outer tiers do not have a great impact (second tier about 0.2%)

Figure 13: Inter-cell interference for adjacent cells

of the interference). Independent of the exact amount of interference, this example shows that the overall energy used within the cell has to be limited. Power control for voice-oriented continuous traffic has dominated the work of most of the researchers for decades. However, the next generation of wireless networks are designed to support packet-oriented data traffic in addition to the *old-fashioned* voice-oriented traffic. Packet oriented traffic brings up new problems for the TPC which are quite different from voice traffic.

In Bambos and Kandukuri (2000) it is shown that packetized data without delay constraints can be sent in dependency of the channel state. If the wireless terminal has to invest too much power to transmit the packet successfully, it could also wait and send this packet later when channel conditions are good. This situation is referred to as *back off*. In the back-off case the delay of the packet will increase—a situation which is not allowed for voice oriented services (only small buffering can be tolerated in real time systems). In a nutshell, data communication introduces a new degree of freedom; the *trade-off between power consumption and delay constraints*. In consideration of this new degree of freedom, Bambos and Kandukuri (2000) presented a new protocol approach for adaptive power control, which also takes delay constraints of packets into account. We will refer to this protocol in the section entitled “Classification of Enhanced CDMA Systems.”

Spreading Sequences

The proper choice of spreading sequences enables multiple access capability for spread-spectrum based wireless communication systems. As already discussed, a sequence is a non-ambiguous identification for a transmitter-receiver pair. As practical sequences are not ideal, their election will have a great impact on the performance of a CDMA network. Spreading sequences can be divided into *orthogonal* and pseudo-noise spreading sequences. This section gives a comprehensive overview of spreading sequences of CDMA systems. The differences between pseudo-noise and orthogonal spreading sequences in terms of auto- and cross-correlation functions are then discussed. The properties of spreading sequences to accomplish multiple access capability are also investigated. Furthermore, the sets of spreading sequences for multi-code CDMA are finally discussed.

As already mentioned, in a spread-spectrum communication system the original information signal

with bandwidth W_l is *spread* to a much larger transmission bandwidth W_{ss} using spreading sequences. At the receiver side, the replica of this spreading sequence is used to recover the original information. In cellular radio communication, multiple access capability is achieved by taking advantage of the autocorrelation and cross-correlation properties of the spreading sequences. Good autocorrelation and cross-correlation properties are instrumental for allowing reliable identification and detection of particular users as well as enabling user separation in a multiple access environment. Such systems are referred to as code division multiple access (therefore, the spreading sequences are also called code sequences in the literature). A spreading sequence consists of C units called *chips*. The chips are two-valued (e.g., bipolar). The autocorrelation function of a spreading sequence reflects the similarity of this sequence with a replica of itself delayed by a time gap τ_{gap} . For a given time gap $\tau_{\text{gap}} = 0$, the autocorrelation value is one, indicating that the sequences are aligned. In any other case $\tau_{\text{gap}} \neq 0$ the autocorrelation value should be small (ideally zero) to minimize the interference among copies of the original signal that are generated and delayed by multi-path propagation. The out-of-phase characteristics of the auto-correlation function has a direct impact on how multi-path replicas affect performance. In fact, when the auto-correlation function is not strictly zero in any out-of-phase position, paths interfere with each other, causing performance degradation. This phenomenon is sometimes referred to as Interpath Interference (IPI). The cross-correlation value of two different spreading sequences represents the interference level for two signals from different wireless terminals with delay τ_{gap} . This value should be as small as possible for all τ_{gap} such that a maximum number of subscribers are allowed in the cell. As a matter of fact, the optimization of the autocorrelation and the cross-correlation cannot be done separately. They depend on each other and typically, the optimization of one side leads to a degradation of the other side.

Orthogonal Sequences. Orthogonal sequences offer zero cross-correlation for $\tau_{\text{gap}} = 0$. If all transmitters are synchronized and no multi-path is considered, the multiple access interference can then be neglected. For any other value of τ_{gap} orthogonal sequences have large cross-correlation values. Therefore, orthogonal sequences are only applied if perfect synchronization can be guaranteed within the system. The autocorrelation properties of orthogonal sequences are also poor if $\tau_{\text{gap}} \neq 0$. This happens if we consider multi-path interference. In such a situation, equalization is applied to recover the original signal.

Several methods to generate orthogonal sequences are presented in Proakis (1995) and Rappaport (2001). As representatives of the orthogonal code family, *Walsh* and *orthogonal Gold* sequences are presented in this section. Walsh sequences can be easily obtained by applying the Hadamard transformation (\otimes defines the Kronecker product), which is given by

$$H_0 = [1], H_2 = \begin{bmatrix} +1 & +1 \\ +1 & -1 \end{bmatrix}, H_{n+1} = H_n \otimes H_n \quad (4)$$

Each row of the Hadamard matrix represents one valid sequence with length N . This leads to an overall number of sequences $N_s = N$. Note that the overall number for PN sequences is much larger. In general the number of achievable codes N_s is limited for orthogonal spreading sequences. Another representative of the family of orthogonal spreading sequences are the orthogonal Gold sequences. Figure 14 shows that orthogonal Gold sequences have reasonable cross-correlation and autocorrelation values. These values are much better than for sequences of the Walsh family.

Pseudo Noise Sequences. PN sequences are binary sequences, which exhibit random properties similar to noise. Within the class of PN sequences, the most popular representatives are *Maximal Length* sequences, *Gold* sequences, and *Kasami* (Proakis 1995) sequences. All sequences can be generated using a **Linear Feedback Shift Register (LFSR)**, which is built by f feedback-taps (Golomb 1992). Sequences generated with a LFSR having the maximum possible period length for an f -stage shift register are called *maximal length* or simply *m-sequences*. The length of an *m*-sequence can be proven to be $2^f - 1$. The number of possible codes depends on the number of possible sets (also called *primitive* irreducible generators) of feedback-taps. Golomb (1992) showed that the overall number of sequences generated by a LFSR of degree f equals

$$N_s(f) = \frac{2^f - 1}{f} \prod_{i=1}^k \frac{P_i - 1}{P_i}, \quad (5)$$

where P_i equals the prime decomposition of $2^f - 1$. Table 2 provides the sequence length of a given degree f and the resulting number of achievable code sequences (see Stahnke 1978 for higher values of f). *m*-sequences have three important properties: (1) the balance property (the number of ones and the number of zeros differ by at most one), (2) the run length property (half the runs of ones and zeros have length 1, and $1/2^k$ length k for $k < n$) and (3) the shift-and-add property (combining two shifted replicas of an *m*-sequence yields another valid *m*-sequence). The periodic autocorrelation function of an *m*-sequence is only two-valued:

$$\Phi_{CC, mseq} = \begin{cases} 1 & k = l \cdot N \\ -\frac{1}{N} & k \neq l \cdot N \end{cases} \quad (6)$$

m-sequences have good autocorrelation properties, while the cross-correlation properties are very poor compared to Gold sequences. Gold sequences can be achieved by combining two *preferred m*-sequences. Different Gold sequences are achieved by combining one *m*-sequence with a delayed replica of another *m*-sequence. This gives an overall number of Gold sequences of $2^f + 1$ (considering two *m*-sequences and the possibilities of combination $2^f - 1$). The cross-correlation function $\Phi_{CC, gold}$ is three-valued $\{-t(f); -1; t(f) - 2\}$ with

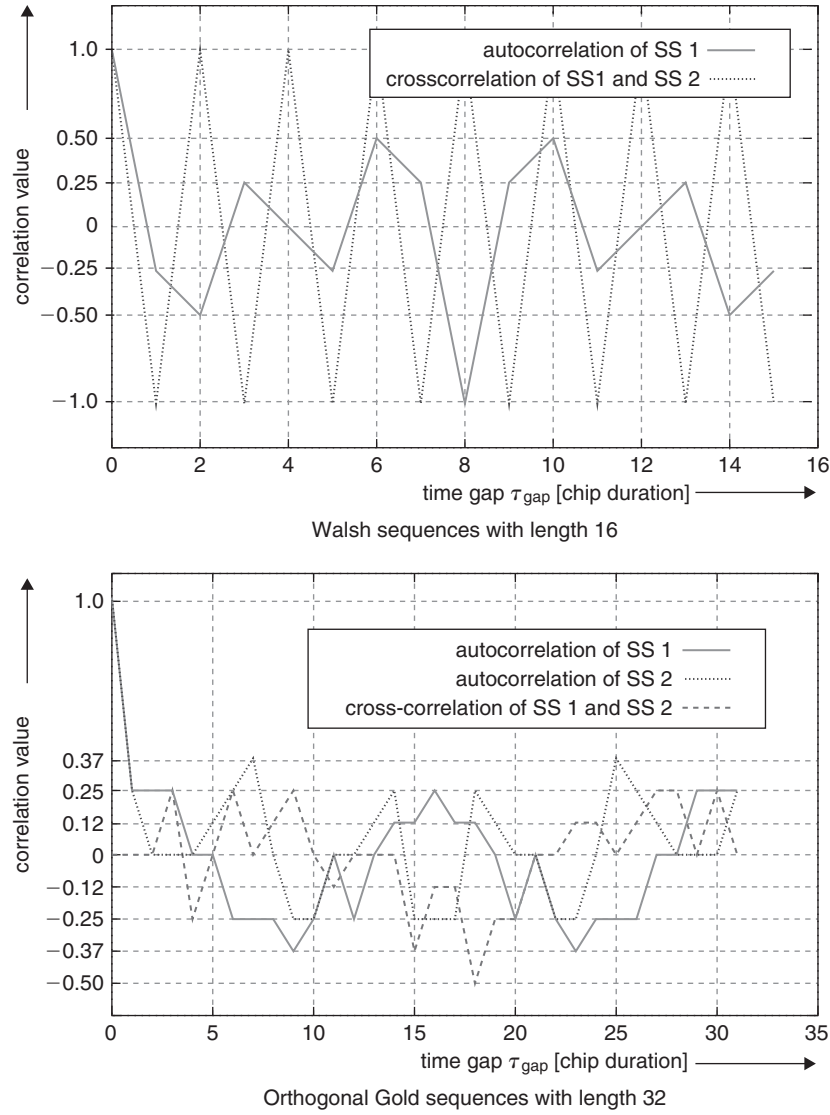

Figure 14: Auto- and cross-correlation function for Walsh and orthogonal Gold sequences

Table 2: Spreading Sequence Length with Related Number of Maximal LFSR (degree f) Spreading Sequences

f	2	4	6	8	10	12	14	16	18	20
P_i	3	15	63	255	1023	4095	16383	65535	262143	1048575
N_s	1	2	6	16	60	144	756	2048	8064	24000

$$t(f) = \begin{cases} (1 + 2^{\frac{f+1}{2}}) \cdot 2^{-f} & \text{if } f \text{ odd} \\ (1 + 2^{\frac{f+2}{2}}) \cdot 2^{-f} & \text{if } f \text{ even} \end{cases} \quad (7)$$

Gold (1967) showed that the cross-correlation between these sequences is uniform and bounded. Combinations of Gold sequences are used to produce the so-called *Kasami* sequences. Kasami sequences have optimal cross-correlation values achieving the Welch lower bound (Kasami 1996). Therefore, Kasami sequences are

promising candidates for spreading in W-CDMA. The scaled cross-correlation function $\Phi_{CC, \text{kasami}}$ is also three-valued $\{-1; -2^{1/2}; -1; 2^{1/2}\}$. The auto- and the cross-correlation function for m -sequences, Gold sequences and Kasami sequences are depicted in Figure 15. For these specific examples it is shown that cross-correlation for m -sequences equals $(-1/16; 1)$, while Gold and Kasami sequences, which are three-valued, give $(-9/35; -1/35; 7/35)$ and $(-9/63; -1/63; 7/63)$ respectively. Moreover, the figure gives a first qualitative estimate for auto- and cross-correlation.

Figure 15: Auto- and cross-correlation function for m -sequences, Gold sequences, and Kasami sequences

Whenever network synchronism can *not* be achieved, PN sequences should be employed. These sequences are easy to generate and offer reasonable cross-correlation and autocorrelation values. For synchronous systems, orthogonal codes should be used. In cellular wireless communication, orthogonal codes should be used for the down-link and PN sequences should be used for the up-link.

Classification of Enhanced CDMA Systems

Adaptive Power Control (APC) in CDMA systems is one way to obtain heterogeneous QoS support. In contrast to recent power control mechanisms, which were designed to assign equal power to the wireless terminals, adaptive power control assigns power related to the QoS requirements. Another subgroup of the enhanced CDMA systems are **Multi-Rate** CDMA systems. These are the only systems that are allowed to change their rates instantaneously and offer variable bit rates. The specific schemes of this sub-group are **Fixed Spreading Gain (FSG)**, **Variable Spreading Gain (VSG)**, and **Multi-Code** CDMA. In contrast to Single-Code CDMA systems, Multi-Code systems support multiple times the basic bit rate. A more detailed description is given later in this section.

Adaptive Power Control. As outlined above, the power control is designed to overcome the near-far effect and tries to control the received power at the WTs. Furthermore, another goal of the power control is to increase the system capacity. Under the assumption that all wireless terminals require the same QoS (e.g., data rate, error probability, etc.), the power for each of the terminals is controlled such that sender's signals are received at the base station with the same power. This is the power control algorithm for voice-oriented services.

To support time-variable QoS, the power level of each terminal was identified in Yan and Messerschmitt (1994), Wu and Kohno (1996), Morikawa et al. (1997), and Yan and Messerschmitt (1995) as a controllable parameter. The proposed approaches dynamically adapt the QoS requirements with power control schemes. As an example, we assume k wireless terminals. Suppose that terminal $i = 1$ has the highest QoS requirements QoS_1 with power level P_1 . All other terminals adjust their power level P_i according to the TPC's commands. The power level for WT i is given by

$$P_i = P_1 \cdot \frac{QoS_i}{QoS_1}. \quad (8)$$

During the transmission process, the power is adjusted depending on the channel state to achieve a required SINR; e.g., if the channel becomes worse (higher interference) the power level is increased to stabilize the SINR. The advantage of such a system is that it can be easily integrated into existing CDMA systems. Adaptive power control is a strong candidate for time-variable QoS support. In contrast to the VSG and Multi-Code approaches, adaptive power control support does not include variable bandwidth.

Fixed Spreading Gain. In the **Fixed Spreading Gain (FSG)** approach (Immaneni and Capone 2000), the spreading gain of each bit stream is maintained constant. The chip duration is also maintained constant. The users vary the transmission time to adapt the variable bit rate requirements. The low rate users transmit for a shorter time as opposed to the higher rate users. It can be seen that the lower rate users suffer from more multi-access interference from the higher rate users, because the higher rate users transmit for longer time. However, the higher rate users suffer from multi-access interference for a shorter time. Hence, the performance for higher rate users is better than for lower rate users. To compensate for this degradation in performance, the lower rate users transmit with more power to increase their signal to interference ratio.

Variable Spreading Gain. The **Variable Spreading Gain (VSG)** approach (I and Sabnani 1995) offers the possibility to achieve flexible data rates. Under the assumption that the bandwidth for transmission is fixed, the spreading gain is reduced as the information bit rate increases, and vice versa. Changing the spreading gain has an impact on the energy per bit ratio. If the transmission power is fixed, an increased data rate leads to a smaller energy per bit ratio (leading to a higher bit error probability). Therefore, the VSG approach is coupled with a variable power control entity to satisfy the same SINR for wireless terminals with different bit rates. In case the transmission power is adapted to the transmission rate, high data rate terminals will influence low data rate terminals. Note that different terminals with the same SINR requirement can be accommodated by allocating power proportional to the terminals' data rates.

$$P_i = P_1 \cdot \frac{R_i}{R_1} \quad (9)$$

Whenever the transmitter changes the spreading gain, the receiver has to be informed about this change. This results in an increased signaling overhead. Because the power level varies according to the chosen data rate, the TPC will also add some more signaling overhead. In the case of short spreading sequences, VSG-CDMA systems suffer from multi-path interference, because of **Inter Symbol Interference (ISI)**. If we consider a constant delay spread for the wireless link, the same number of chips are influenced, but the number of influenced symbols depends only on the spreading gain. In Ojanpera and Prasad (1998), it is shown that with VSG the high power terminals degrade the performance of low power terminals. In addition, high power terminals are using shorter spreading codes and therefore the spreading sequences have a significant impact on the system performance. Thus it might be useful to implement higher bit rates with Multi-Code CDMA systems (Ojanpera and Prasad 1998).

Multi-Code Code Division Multiple Access. In this section, the capability of WTs to transmit and receive on multiple CDMA channels by means of Multi-Code-CDMA is discussed. We consider different families of spreading

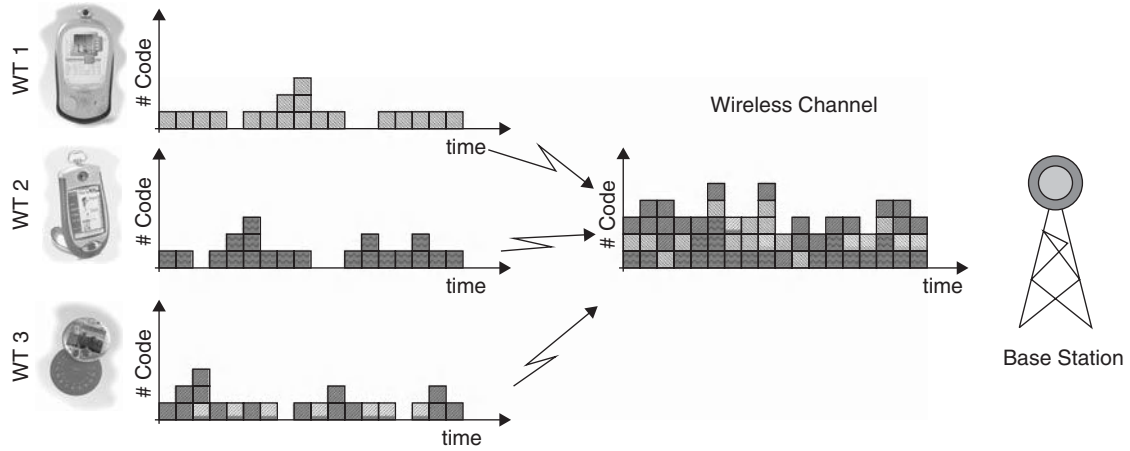

Figure 16: Statistical multiplex effect on the air interface of CDMA

sequences with their need for signaling for Multi-Code-CDMA. We then compare the Multi-Code-CDMA approach with the enhanced power control and the variable spreading gain approach. In Figure 16 the statistical multiplex effect of the air interface is depicted. For illustrative purposes we choose three WTs which transmit packets over the wireless link to the BS. For this example we assume that WTs are able to transmit also on multiple channels. This example shows how the three different *streams* of each WT with highly variable load are multiplexed on the air interface.

Multi-Code-CDMA (Lin and Gitlin 1995) can support a basic bit rate as well as integer multiples of the basic bit rate. In Multi-Code-CDMA, a high data rate is split into smaller data rates. Each small data rate is then spread by a different code sequence over the entire coherent bandwidth. All spread signals are modulated and transmitted over the wireless link. Figure 17 depicts a Multi-Code-CDMA transmitter.

The choice of spreading codes is very important to keep self-interference as low as possible. Because orthogonal sequences are used, the number of overall sequences within the cell is limited. In case one terminal wants to transmit on more channels, it has to request these channels from a centralized code depository. Thus, delay-sensitive services are hard to support. Orthogonal code sequences do benefit from the fact that self-interference does not exist as long as the system is synchronous. Synchronism exists only within the down-link and

between channels of one wireless terminal in the up-link. In asynchronous systems, orthogonal codes lead to poor system performance.

The other choice of codes are PN code sequences. The number of these codes is large; however, the interference among the channels is high. Lin and Gitlin (1995) proposed to use pseudo random sequences to distinguish between the asynchronous up-link transmissions of the different wireless terminals. Additionally, they proposed to use orthogonal sequences to distinguish between synchronous up-link transmissions of a given wireless terminal. This approach gives a large total number of codes in conjunction with low self-interference between the parallel channels of a given wireless terminal. Further improvements are achieved when a central entity assigns the terminal specific pseudo random sequences (Stahnke, Boche, Fitzek and Wolisz 2000). Note that this does not require additional overhead for bit rate changes because the total number of codes is large and the codes are assigned to the terminals during link establishment. The hardware complexity, however, is higher as rake receivers are required for each channel to suppress multi-path interference. It is noted in Ojanpera and Prasad (1998) that the Multi-Code-CDMA approach is slightly more promising for multi-rate CDMA than the Variable Spreading Gain approach. It is argued that the former has a smaller signaling overhead and lower multi-path interference.

A brief overview of benefits and drawbacks of the three approaches for supporting time-variable QoS is given

Figure 17: Multi-Code CDMA sender with the carrier frequency f_c , the spreading sequence c_m , the discrete input $a_m[k]$, and the analog output $s_m(t)$

Table 3: Enabling CDMA Technologies with Their Benefits and Drawbacks for Time-Variable QoS Support

	Enhanced Power Control	Variable Spreading Gain	Multi-Code CDMA
multi-path interference	no further impact	high rate \rightarrow high ISI	no further impact
multiple access interference	\rightarrow power level	\rightarrow bit rate	\rightarrow number of channels

enable higher data rates	no	yes	yes
granularity	—	high degree depends on spreading codes	multiple of CDMA channels
applied in	—	UMTS FDD [1]	UMTS TDD [1]

in Table 3. Note that combinations are possible to better exploit their benefits. In Ramakrishna and Holtzman (1998), the performance in terms of SINR and BEP of VSG and the Multi-Code-CDMA systems is compared. Authors in Ramakrishna and Holtzman (1998) summarize that whether a wireless terminal uses one of these approaches, it has an identical effect on both the SINR and the BEP of the other wireless terminals in the system. Furthermore the authors remark that multi-code systems have the disadvantage of instantaneous amplitude variations (for VSG they exhibit a constant instantaneous amplitude) and additional hardware complexity. In Webb, Huang, and Brink (1997) methods are introduced which reduce the hardware complexity of Multi-Code-CDMA systems significantly. Nevertheless in Ojanpera and Prasad (1998) it is claimed that multi-rate can be implemented with Multi-Code-CDMA in a slightly better way than with VSG, because of higher signaling overhead and lower multi-path interference rejection of the latter. Adaptive power control approaches have no multi-rate capability. For all approaches a high performance power control entity has to be implemented. Henceforth we use the Multi-Code-CDMA approach.

Wireless CDMA Channels

In the following, we investigate the characteristics of the CDMA uplink wireless channel. We concentrate on the usage of **Pseudo-Noise (PN)** sequences. In particular the CDMA based bit error probability for non-orthogonal spreading sequences depends on the overall number of active channels in one cell. Therefore, we give a detailed overview of the major bit error probability models and the impact on throughput and capacity.

Bit Error Probability in CDMA

Direct Sequence (DS) CDMA communications systems achieve their multiple access capability by assigning each

WT a unique spreading sequence (see Section 1.3.3). Because of different distances between WT and BS the transmitted signals arrive at the BS with random delays τ , carrier phases ϕ and power levels P . The *exact* error probability depends on the particular spreading sequences used by the WT, random amplitude, delay and carrier phase. The calculation of the exact **Bit Error Probability (BEP)** for a CDMA system with **Pseudo-Noise (PN)** sequences is difficult to evaluate. Therefore a variety of different error models based on Gaussian approximations can be found in Rappaport (2001). The design of the spreading sequences is not taken under consideration with the Gaussian approximations.

As given in Figure 18, we assume that J WTs simultaneously access the wireless channel. We further assume that each bit is spread by $G_{\text{Spreading}}$ chips. The transmitted signal $s(k)$ is assumed to be a sequence of two independent, identically distributed random variables (chips), where the probability of each variable is given by 1/2. Therefore we use the classical expression for uncoded BPSK modulation considering additive

**Figure 18:** General CDMA channel

white Gaussian noise with power spectral density I_0 and energy per bit E_b (given in Equation 10) to calculate the bit error probability of a DS CDMA system. Assuming that all WTs arrive chip synchronously but phase asynchronously at the receiver side, the bit error probability $p_{biteror}^{BPSK}$ results in

$$p_{biteror}^{BPSK} = Q\left(\sqrt{2 \cdot SINR}\right) = Q\left(\sqrt{\frac{2 \cdot E_b}{I_0}}\right). \quad (10)$$

where $Q(x)$ is related to the complementary error function and is defined as

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-t^2/2} dt. \quad (11)$$

The energy per bit E_b can be calculated by dividing the received signal power P_s by the data rate R_i .

$$E_b = \frac{P_s}{R_i}. \quad (12)$$

To calculate the power spectral density I_0 , we assume perfect power control for all WTs. Perfect power control implies that all signals arrive at the receiver with the same power level. Moreover, multi-path interference is not considered in this model. Thus the noise power spectral density I_0 is influenced by three different terms as depicted in Figure 18. The additive white Gaussian noise power spectral density N_0 is characterized by the communication system, while the jammer density J_0 depends only on the jammer's hardware and his jamming technique (broadband or band limited). For simplicity we assume only broadband jamming. The last factor is made up of other active WTs which are using the channel simultaneously. The sum over the energy of all other WTs will be spread over the whole spreading bandwidth W_{ss} . The inter-chip interference was not taken into account within our assumptions. Because of the perfect power control assumption each signal will arrive with the same power level, which results in a very simply equation for the noise power spectral density I_0

$$I_0 = \frac{I}{W_{ss}} = \frac{P_s \cdot (k-1)}{W_{ss}} + N_0 + J_0, \quad (13)$$

where I is the overall noise power by all other WTs and k denotes the number of active channels within the cell. According to a Single-Code CDMA (SC-CDMA) system we assume one channel per WT, and if α_i represents the activity of WT i , k is generally given by $k = \sum_{j=1}^J \alpha_j$. Using Equations (10), (12), and (13) we obtain:

$$p_{biteror} = Q\left(\sqrt{\frac{2 \cdot \frac{P_s}{R}}{\frac{P_s \cdot (k-1)}{W_{ss}} + N_0 + J_0}}\right). \quad (14)$$

$$G_{Spreading} = \frac{T_B}{T_C} = \frac{T_C}{\frac{1}{T_B}} = \frac{W_{ss}}{R_i}. \quad (15)$$

The spreading gain has been defined as the number of chips per bit for a DS CDMA system. Thus it can be calculated by the ratio of T_B and T_C . This is equivalent to the ratio of W_{ss} and R_i .

$$p_{biteror} = Q\left(\sqrt{\frac{2 \cdot G_{Spreading}}{k-1 + \frac{N_0 \cdot W_{ss}}{P_s} + \frac{J_0 \cdot W_{ss}}{P_s}}}\right). \quad (16)$$

The complementary error function Q function can be transformed in the *erfc* function

$$erfc(\alpha) = 2 \cdot Q(\sqrt{2} \cdot \alpha). \quad (17)$$

We model both the background noise and the jamming (in a friendly environment the jammers can also be neglected) as b wireless terminals that transmit all the time, resulting in a decreased SINR. This simplification leads to the simplified Equation (18), which can be found in Noll (1999)

$$p_{biteror}(k) = Q\left(\sqrt{\frac{2 \cdot G_{Spreading}}{k-1+b}}\right). \quad (18)$$

An improved Gaussian approximation has been derived by Holtzman (1992) and applied in Buehrer and Woerner (1996). The bit error probability for the improved Gaussian approximation is given in Equation (19). The calculations for the bit error probability are still simple enough but lead to quite accurate results. In Rappaport (2001) it is claimed that the improved Gaussian approximation should be used, if the number of WT is small or the spreading gain $G_{Spreading}$ is large.

$$p_{biteror}^{IMP}(k) = \frac{2}{3} Q\left(\sqrt{\frac{3 \cdot G_{Spreading}}{k-1+b}}\right) + \frac{1}{6} Q\left(\frac{G_{Spreading}}{\sqrt{\frac{(k-1+b)N}{3}} + \sqrt{3}\sigma}\right) + \frac{1}{6} Q\left(\frac{G_{Spreading}}{\sqrt{\frac{(k-1+b)N}{3}} - \sqrt{3}\sigma}\right)$$

$$\sigma^2 = (k-1+b) \times \left(\frac{23}{360} \cdot G_{\text{Spreading}}^2 + \left(\frac{1}{20} + \frac{k-2+b}{36} \right) (G_{\text{Spreading}} - 1) \right). \quad (19)$$

Packet Error Probability in CDMA

Considering the bit error probabilities in (18) we give the **Packet Error Probability (PEP)** for a packet data unit of the length L_{PDU} [bit] in Equation (20) under the assumption that the bit errors occur without correlations.

$$p_{\text{pkterror}}(L_{\text{PDU}}, k) = 1 - \left(1 - p_{\text{biterror}}(k)\right)^{L_{\text{PDU}}} \quad (20)$$

If we assume a coding scheme that allows us to correct e bit errors, the packet error probability becomes smaller and is given in Equation (21) (Gu and Olafson 2000, Poydoras 1994, Chang and Lin 1999).

$$p_{\text{pkterror}}(e, L_{\text{PDU}}, k) = 1 - \sum_{i=0}^e \binom{L_{\text{PDU}}}{i} \times \left(1 - p_{\text{biterror}}(k)\right)^{L_{\text{PDU}}-i} \left(p_{\text{biterror}}(k)\right)^i \quad (21)$$

More advanced coding schemes can be found as given by Viterbi in Viterbi 1990.

Synchronization

In any spread-spectrum system, there exists a fundamental operation that needs to be carried out in order for the receiver to demodulate and decode the target signal. This operation is *synchronization* and it needs to be done in all systems mentioned (e.g., DS, FH, TH, and hybrid combinations of them). Throughout this chapter, we have assumed that the receiver was synchronized to the incoming signal through this vital operation is sometimes difficult to achieve in practice. We briefly referred to the problem of synchronization in frequency-hopping systems in the initial example of Hedy Lamarr's invention. It is clear that in any frequency-hopping spread-spectrum system, the receiver needs to synchronously follow the hopping pattern used by the transmitter. Because this chapter deals with CDMA systems, we will here concentrate mainly on synchronization of direct sequence spread spectrum systems. Synchronization of DS systems is normally done in two stages, namely *initial synchronization*, also known as *code acquisition*, and *code tracking*. The former refers to the task of bringing the locally generated spreading sequence into phase with the received one within the accuracy of one chip, while the latter refers to the task of bringing and keeping the remaining difference to a null value.

Code Acquisition

This operation can be seen as an initial procedure for coarse alignment of the local and received sequences. The alignment of sequences is essential to allow despreading of the received signal. The receiver can be seen as a correlating unit which computes the autocorrelation

function of the spreading sequence. There are several strategies for the initial code acquisition. The most common approach to code acquisition is based on a *serial search*. The receiver can control the phase of the locally generated spreading sequence in quantized steps. Typically the step size is one chip, though some fractional values are sometimes used (e.g., $1/4$, $1/2$). The serial search procedure starts by correlating the sequences at an arbitrary phase position and gradually advancing the local sequence phase by one unit step. Such a procedure is repeated until the correlating unit outputs a high value, indicating that the received and local sequences are in phase. Note that mathematically the receiver is computing the auto-correlation function of the spreading sequence. Every possible relative position between these sequences is denominated a cell and the total number of cells to be searched forms the so-called *uncertainty region*. If the spreading sequence has Q chips and we search in steps of one chip, then the length of the uncertainty region is also Q . In principle we would need to test the Q cells sequentially and then select the cell with highest correlation result as that corresponding to the synchronized position. In order to expedite the process, we usually use a *threshold* to compare it with the correlation result, and whenever the threshold is exceeded we declare the signals synchronized. Of course, we would like to achieve the synchronization state as quickly as possible. This is important because users switching on their WTs would like to be wirelessly connected as soon as possible. In some occasions, very fast acquisition times are required, as in the case of packet communications. For such cases the use of *matched filters* is common where the filters are matched to the spreading sequences. Due to reasons of implementation complexity, matched filter solutions are typically used with short spreading sequences. Code acquisition is a stochastic process because it is influenced by noise and interference; hence, it cannot be deterministically modelled. In the above example, and considering a single path channel, there is a single cell where the code sequences are in line, and it referred to as the *synchro cell*. The rest of the $(Q-1)$ cells are called *nonsynchro cells*. At the synchro cell, synchronization would be declared with a given probability of detection P_D , a figure that which typically will be close to unity. P_D represents the probability that the auto-correlation result exceeds the threshold value. However, due to noise and interference we may miss the synchro cell, with a probability $1-P_D$. In such a case the serial search will move on until we again are in the synchro cell position and we have a new chance to detect synchronization. In each of the $(Q-1)$ nonsynchro cells, we may erroneously detect synchronization (due to the effects of noise and interference) with a probability P_{FA} (probability of false alarm) or we may recognize each of them as non synchronized cells with a probability $(1-P_{FA})$. The probabilities P_D , P_{FA} , the integration time (the time needed to correlate the sequences) and the threshold value are very much dependent on each other, and together with the step size and length of the uncertainty region, determine the statistics of the code acquisition process. The typical performance measures of code acquisition are the mean acquisition time and its variance. In general, code acquisition is a very difficult and

critical task that needs to be done in adverse noise and interference conditions as the processing gain advantages are only available once the system is synchronized.

Code Tracking

Code tracking, also known as fine code synchronization, is a operation subsequent to code acquisition which aims to reduce and maintain the possible resulting fractional misalignment to zero. Code tracking is usually performed by a delay lock loop (DLL) which virtually tracks the temporal variations of the radio channel. The most common approach to code tracking is the early-late DLL, which correlates the received signal in two parallel *early* and *late* branches, with advanced and retarded phase delay offsets, respectively. A fractional timing offset between the local and received sequences will result in different correlation values at the early and late correlator outputs. These signals are compared and then used to control the phase of the local sequence generator in the direction of reducing the phase delay offset between sequences to zero. In other words, the timing offset between the sequences is estimated from the energy difference between the early and late correlator outputs. The code phase error has a symmetric characteristic with respect to the phase detector output, and it is usually referred to as the s-curve. The performance of code tracking can be seriously degraded by the presence of closely spaced multi-path components and (multiple access) interference.

Synchronization in CDMA Networks

In CDMA networks, interference plays an essential role in system performance, and also in synchronization performance. In particular, it is interesting to notice that every time the receiver correlates the local and received sequences, it also computes the sum of cross-correlations between the local sequence and each of the sequences corresponding to other users. Every time that the phase of the local sequence is advanced, this cross-correlation sum will take on a different value and eventually it may exceed the threshold value in non-synchronized cell positions. Multiple access interference could be very large in some cases resulting in situations with very long mean acquisition times, or even worse, sequences that could not be synchronized at all in some extreme cases. Practical CDMA systems exploit rake receivers to resolve several paths, and such a bank of receivers could be utilized already at the initial synchronization stage to acquire a number of strong paths. Once that first path is detected, the receiver can reduce its uncertainty region around that path because the remaining paths are very likely to be in close proximity to the first detected path.

CONCLUSION

In this chapter we reviewed the most relevant aspects of CDMA technology. CDMA is important because it is the underlying technology of the third generation mobile communication systems (3G), currently being deployed and starting to gain market share. Moreover, though future wireless communications are widely assumed to be based on multi-carrier systems, CDMA is tacitly present there too, either used in combination with OFDM systems or

on systems based on multi-carrier CDMA (MC-CDMA) techniques. CDMA is a well understood and practically mature technology with a bright future.

GLOSSARY

- CDMA:** Code Division Multiple Access (CDMA) allows multiple users to access the same spectrum at the same time. The users are unambiguously distinguished by their unique associated spreading code.
- DS:** In case of direct sequence (DS) spreading, the spreading code is combined with the information signal by a modulo-2 operation.
- FDMA:** Frequency Division Multiple Access (FDMA) separates users in frequency.
- FH:** The information signal hops over different frequency bands in case of the Frequency Hopper (FH).
- MAI:** Multiple Access Interference (MAI) is a composite signal resulting from multiple users accessing the same spectrum at the same time in CDMA networks.
- PN:** Pseudo Noise (PN) sequences are one family of spreading sequences for CDMA.
- Power Control:** Power control is a functionality to adjust the transmit power to an optimal value. It is applied on both mobile and base stations.
- TDMA:** Time Division Multiple Access (TDMA) separates users in time.

INTRODUCTION

Time-division multiple access (TDMA) is a technology for shared medium networks that allows several users to share the same frequency by dividing into different time slots. The users transmit in rapid succession, one after the other, each using their own time slot. The technique allows multiple users to share the same transmission medium using only the required bandwidth (Wikipedia 2005).

TDMA is also a specific second-generation (2G) mobile phone standard—interim standard 136 (IS-136) or digital advanced mobile phone service (D-AMPS)—that uses the same time-share bandwidth technique. In radio systems, TDMA is usually used alongside other multiplexing techniques, such as frequency division multiple access (FDMA) and code division multiple access (CDMA). This can be very confusing because competing 2G standards such as global system for mobile communication (GSM), personal digital cellular (PDC), and integrated digital enhanced network (iDEN) also use the TDMA technique in airwave management and signal processing. Besides cellular applications, TDMA is also used extensively in satellites, local area networks (LANs), physical security systems, and combat-net radios.

TDMA: THE MULTIPLEXING TECHNIQUE

Communication is defined as sending messages using electricity, light, or radio signals from one point to another. Multiplexing is the technique in which two or more independent messages are carried by a single medium. Although the focus is on TDMA, there are two other multiplex accessing techniques: FDMA and CDMA. FDMA is the oldest and is used widely in analog systems. It divides a carrier spectrum into frequency slots, assigning each to a different message. CDMA is the latest technique; each message is assigned and tagged with a unique identifying code, such that the relevant message can be separated out by the intended receiver.

TDMA is a multiplexing technique that allows multiple users to access a common channel without interference

by allocating unique time slots to each user. The user has the entire channel, but only for a brief moment. Time-sharing is far from a novelty. Multitask operating systems apply the same principle by rotating jobs in and out of execution. TDMA divides time into slices and restricts job execution to only one slice at a time. At the completion of each slice, the current job is set aside and another is allowed to execute. Time division can either be performed equally or on demand. Synchronous TDMA gives each incoming signal an opportunity to transmit, proceeding in a round-robin fashion. However, this approach can waste bandwidth because a slot is assigned even if users have nothing to transmit. Synchronous TDMA is the most common technique in wired channels. Statistical TDMA, on the other hand, assigns time slices only to active users. With transmission no longer round-robin, addresses must be included to identify the sender and receiver. Statistical TDMA may be more efficient in bandwidth utilization but requires overhead in address processing. In wireless communication in which bandwidth is limited, statistical TDMA tends to be a more popular technique.

BRIEF HISTORY OF CELLULAR WIRELESS SYSTEMS

The advanced mobile phone system (AMPS) is an analog mobile phone system standard, developed and introduced in the United States during the early 1980s. With exponential growth, cellular systems were already running into capacity limits by the early 1990s. The need to serve more customers simultaneously with the same amount of radio spectrum was considered essential for continued growth and industry survival. Capacity was increased through the development of interim standard 54 (IS-54), a dual-mode digital cellular standard that utilized digitization, compression, and TDMA (Noll 1999). IS-54 was designated by the Telecommunications Industry Association (TIA) and became the leading technology in the United States; meanwhile, GSM was developed by the European Telecommunications Standards Institute (ETSI) and became the dominant standard in Europe and many other countries.

Japan took a different path by adopting the PDC designated by the Association of Radio Industries and Businesses (ARIB) for use exclusively in Japan. Although all of these systems used the TDMA technique, their implementations were different, and, more importantly, they are incompatible with each other.

Qualcomm proposed a cellular system, interim standard 95 (IS-95), based on spread-spectrum technology and CDMA in 1994. Even though the advertised increase in bandwidth utilization had yet to be realized, IS-95 dominated about half of the U.S. licenses. In 1995, the Federal Communications Commission (FCC) licensed the personal communication system (PCS) frequency spectrum to the public. PCS was built upon existing standards but operated between frequency bands 1800 and 1900 MHz. The evolution of IS-54 to IS-136 came shortly after the spectrum was opened up. All PCSs are digital, using either TDMA or CDMA. Hence, IS-136 is also known as PCS TDMA, and IS-95 is known as PCS CDMA. The European GSM is sometimes dubbed PCS 1900. Together, these are the most popular 2G cellular standards.

The future demand for mobile cellular services appears to be nearly unlimited, especially with the mobile Internet upon us. The third-generation (3G) technologies operating at 2 Mbps can turn phones into multimedia players, making it routine to download music and video. Currently, there are several competing 3G standards. The International Telecommunication Union (ITU) is working on the International Mobile Telecommunications-2000 (IMT-2000) initiative, into which all 3G standards will eventually merge. Direct migration to 3G networks is costly and challenging. Most wireless operators are taking an interim stage called 2.5G to achieve data rates up to 114 kbps, as compare to the 9.6 kbps in traditional 2G (see Figure 1). As we explore various TDMA wireless standards in this chapter, network architecture, topology, and cell structure issues will not be covered because they are generic and similar in most cellular technologies. For those interested in these subjects, tutorials are available from the International Engineering Consortium on IS-136 (IEC 2005a) and GSM (IEC 2005b).

IS-136 TDMA STANDARD

TDMA is an important part of the evolution from 1G analog to 2G digital systems. Although IS-136 is not the most

advanced of the 2G systems, it is the first digital TDMA and provides an excellent framework for the illustration of a TDMA wireless cellular system. In fact, TDMA and IS-136 are usually synonymous with each other. Regardless of standards, wireless systems are constantly confronted with two capacity issues: voice/data and control. Similar to AMPS (TIA 1999), IS-54 (TIA 1989) uses frequency ranges at 800 MHz with 30 KHz channels to achieve multiple access by applying TDMA on an FDMA structure. The channels are divided into three time slots carrying digitized voice signals. The addition of the time slots automatically triples the voice capacity available.

IS-136 (TIA 1995) was an enhancement to IS-54 and represented the next-generation TDMA-based PCS system. The analog portion of AMPS was incorporated into the new specification to provide a smooth migration path for analog/digital dual-mode operation. IS-136 was also designed to work dual band on both the 800 MHz and the PCS 1900 MHz frequencies. Whereas IS-54 uses the three time-division channels for voice data only, IS-136 added the digital control channels (DCCs), which enable support for new advanced features such as paging and messaging.

Digitization, Encoding, and Modulation

The basis for all digital communication involves digitization, encoding, and modulation. Digitization is the conversion of analog acoustic voice signal into digital data. As we speak into a microphone, analog audio signals are created. Since the bandwidth for phone systems is limited to 3000 Hz, frequencies below 400 Hz and above 3400 Hz in the audio signal are filtered off. The signal is converted subsequently into a digital value at a rate of 8000 samples per second with 8-bit resolution, resulting in 64 kbps digital data representing the analog voice information using the pulse code modulation (PCM) technique.

After digitization, IS-136 applies data compression with a speech coder to efficiently transmit the signal. A speech coder delineates the digitized signal and filter off patterns that are not characteristic of the human voice. The resulting signal is an approximation of the voice content that can be recreated by the receiving speech decoder. The speech coder characterizes the input signal by looking up a codebook table and selecting the code that most accurately represents the input signal.

PCM, invented decades ago, is not efficient enough for wireless network application. IS-136 uses the vector sum

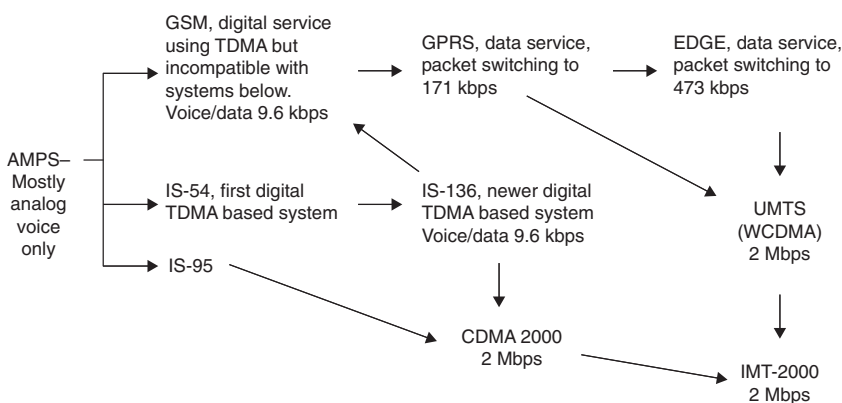

Figure 1: Common cellular wireless system and its migration path

excited linear predictive (VSELP) speech coder, which compresses voice down to 7.95 kbps and achieves an 8:1 compression. VSELP produces a speech frame containing 159 bits every 20 ms. It digitizes the voice's essential elements using digital signal processing (DSP) along with proprietary algorithms to crunch down speech and conserve bandwidth. If a speech segment is lost over the channel, the VSELP decoder can also repair the effect through speech extrapolation.

As data compression technologies develop, improved speech coders have become available. The newest version of IS-136 introduces the enhanced full rate (EFR) algebraic code-excited linear prediction (ACELP) speech coder, which supports "over the air" activation, calling name ID, enhanced handoffs, and priority access to control channels. The coder has an output of 7.40 kbps with 148 bits in a speech frame. The ACELP coder also has a higher sampling rate and offers cleaner, crisper audio quality comparable to landlines under normal channel conditions.

A modulation scheme for the mobile environment must use transmitted power and frequency bandwidth very efficiently because the mobile station is both power- and bandwidth-limited. IS-136 uses $\pi/4$ differential quadrature phase shift keying (DQPSK) for signal modulation, which is a technique that alternates between two quadrature constellations. The constellations are offset by $\pi/4$ radians, or 45 degrees, with successive symbols taken from the two constellations every other period. Phase shift is reduced from a maximum of 180 degrees to 135 degrees. DQPSK can be detected using a coherent detector, a differential detector, or a discriminator that reduces the complexity of receiver structures. DQPSK also has a high tolerance to dispersion and nonlinearities, as well as a narrow spectrum that enables close channel spacing.

Frame Structure, Slot, and Traffic Channel

A channel is simply a communication path between two devices. Typically, two radio frequencies make a cellular

channel—one is needed to transmit and the other to receive. Sound waves are converted and transmitted as digital numbers or bits, but we also need to define the data structure of the channel: frame and slot. A frame is the complete unit of data transmitted between network points, which can be long or short. Apart from data, a frame also carries information about itself such as address, length, and status. In time-division multiplexing, a frame is a complete cycle of events within the time-division period. Frames hold slots, which in turn hold channels.

Slots hold individual conversation as well as signaling and controlling information within the frame. TDMA places several calls on a single frequency, separating the conversations in time. Each caller occupies a predetermined amount of time in an assigned time slot on an assigned radio frequency. Calls are combined into a digital stream, and then assigned and delivered into the right time slots on the right frequency at the right time. Radio channels in IS-136 are 30 KHz wide and identical to AMPS. Each frame is 40 ms, divided into six slots. IS-136 traffic is always full-rate, using two slots for one call. Half-rate traffic can be implemented using one slot, but this is not popular due to low quality and is unnecessary given the available capacity. A frame is divided into two blocks, with each block carrying three slots. Data rate is 48.6 kbps, with each slot transmitting 324 bits one way in 6.67 ms (see Figure 2).

The mobile station (MS) must have the transmission power off except for the assigned time slot following an assigned transmit power profile. The base station (BS)—the beacon carrier—must transmit on all six time slots at the same power level. When there is no traffic at a particular time slot, BS uses a dummy burst to fill in on the unassigned traffic. The base transmitter may adjust the transmit power level separately in each time slot, except on the beacon frequency. Thus, a higher power may be used in a time slot that is transmitting to an MS in the outer part of the cell, while a lower power may be used in a slot transmitting to an MS that is close by, improving

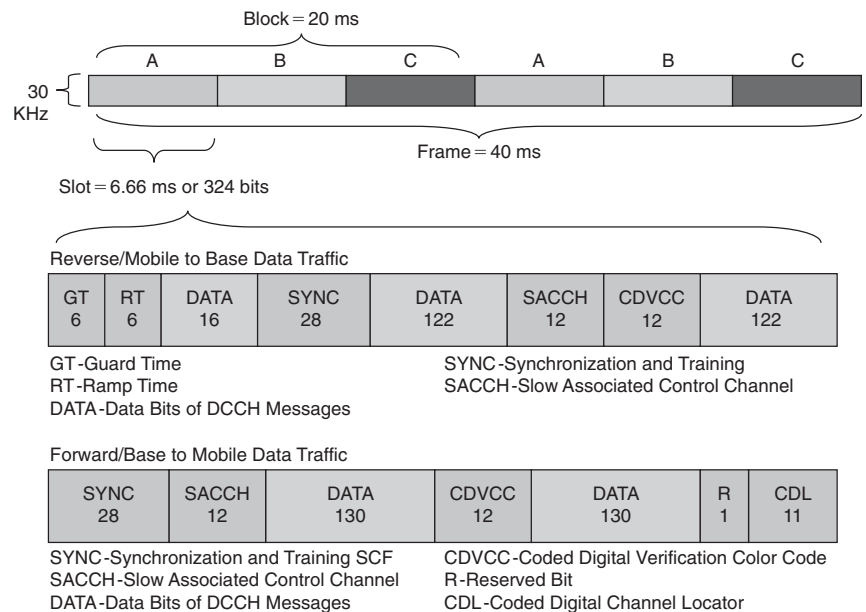

Figure 2: IS-136 frame, slot, and digital traffic channel structure

the overall interference level with other cells in the system.

Voice conversation is carried in a slot's data field. Six slots make up one frame, and two slots form a voice circuit or digital traffic channel (DTC). Bandwidth is used only partially for data—260 out of the 324 bits—because control is needed for proper DTC operation (the numerical values in Figure 2 refer to bits). Forward and reverse DTC have different structures. Definitions of the subchannels are as follows:

- Guard time (GT): period between time slots; keeps data bursts separated
- Ramp time (RT): period during which transmitter goes from a quiet state to full power
- DATA: the data bits of the actual voice conversation in digitized form
- Synchronization (SYNC): slot must synchronize with all others and the master clock
- Coded digital verification color code (CDVCC): a unique 8-bit code that simulates a marker to ensure that the correct MS is communicating with the proper BS (because frequencies are reused in the cellular system)
- Slow associated control channel (SACCH): used to pass control information (e.g., signal strength)
- Coded digital control channel locator (CDL): indicates the range of frequencies in which DCCH can be found in forward DTC only
- R: reserved

The IS-136 standard has several methods of transferring control information for the DTC, including in-band signaling using fast associated control channel (FACCH) and out-of-band signaling using SACCH. Whereas in-band signaling replaces voice data, out-of-band signaling is sent with the data. SACCH is a continuous stream of information sent using dedicated bits in each slot that coincide with the slot's voice traffic and do not affect data transmission. However, the transmission rate for SACCH is slow. For rapid or urgent delivery, control is sent via FACCH. FACCH runs in a blank-and-burst mode; the voice traffic in a slot is “blanked,” and a “burst” of data is sent instead. FACCH is used during handoff or when the SACCH cannot send information fast enough. Whenever FACCH overrides

the voice signal, speech quality is degraded. However, IS-136 does run more efficiently because the MS does not need to return to the control channel. The SACCH and FACCH designs optimize bandwidth utilization for continuous speech and control signaling.

Control, Logical Channels, and Superframe

The ability to use DCCH is an important enhancement for IS-136. DCCH increases paging capacity and allows the sharing of traffic and control on the same channel. Whereas SACCH and FACCH in DTC perform call association, DCCH is used for administration and services. Thus, DCCH forms the platform for a new generation of wireless features such as message services, sleep mode, private systems, and enhanced security.

In contrast to AMPS and IS-54, IS-136 has no preassigned frequency for control channels. The system can choose any frequency in each cell for this purpose, or it may change the frequency dynamically. When an IS-136 mobile phone enters a cell, carriers are scanned until a sufficiently strong signal is received such that the proper frequency for DCCH from the forward DTC CDL subchannel can be located. IS-136 does not need to exhaustively scan all the frequencies in that cell to find the proper setup channels.

IS-136 DTC and DCCH both use the same frame/slot structure (see Figure 3). In general, only one slot pair, slots 1 and 4, is required for DCCH in each cell. The numerical values in Figure 3 refer to bits, and forward and reverse DCCH have different structures. Definitions of individual subchannels are as follows:

- Guard time (GT): see DTC definition
- Ramp time (RT): see DTC definition
- DATA: data bits for DCCH messages
- Synchronization (SYNC): see DTC definition
- Preamble (PREAM): used for timing, and by the BS to set the received amplifier to avoid signal distortion
- Additional synchronization (SYNC+): additional bit pattern that provides additional synchronization information

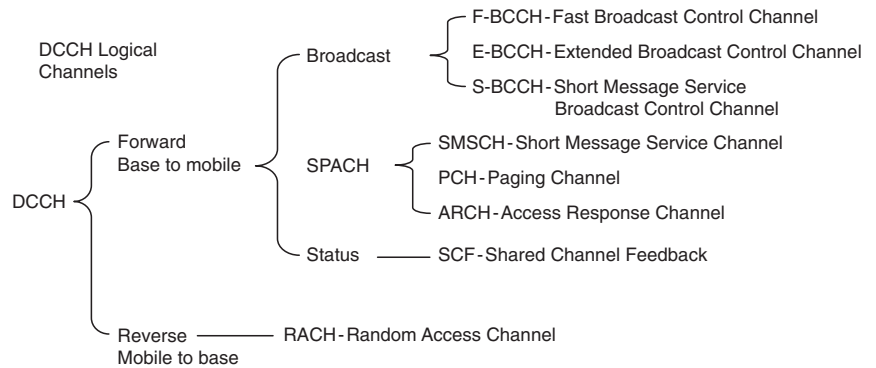

Figure 4: IS-136 DCCH logical channels

- Shared channel feedback (SCF): a collection of flags used as a method of control and to acknowledge send from MS to BS
- Coded superframe phase (SCFP): indicates to the MS which frame in the superframe is currently being transmitted

In order to organize and facilitate information flow across the cellular interface, logical channels are defined in the IS-136 DCCH to perform, sort, and prioritize signaling functions (see Figure 4). A logical channel is formed by a given slot in the sequence of frames and may be formed by the same slot number in successive frames. However, the same slot in successive frames does not necessarily belong to the same logical channel.

The multiplexed broadcast (BCCH) channel is designed to carry system configuration and rules information that the MS must follow for system access. BCCHs are multiplexed onto the DCCH forward channel and divided into the following three channels:

- Fast broadcast channel (F-BCCH): used for mandatory and time-critical information such as the system ID registration and access information; F-BCCH has a fixed repetitive cycle
- Extended broadcast channel (E-BCCH): used to carry supplementary information that is not time critical (e.g., neighbor cell lists)
- Short message service broadcast channel (S-BCCH): used to broadcast messaging service

The multiplexed point-to-point short message service messaging, paging, and access-response (SPACH) channel is used to communicate with a specific phone with logical channels as follows:

- Short message service channel (SMSCH): carries tel-service data to and from the MS
- Paging channel (PCH): carries system pages to the MS
- Access response channel (ARCH): provides system response to phone queries and administration information from the base to the MS

The random access channel (RACH) is a shared channel and the only reverse DCCH. It can be used, for example,

to respond to an authentication request. RACH is controlled and acknowledged by shared channel feedback (SCF) on the forward DCCH. SCF provides status on all reverse time slots and informs all MSs of the usage at any particular time.

Superframe and hyperframe are used to multiplex logical groups of information together and provide a known repetitive, ordered sequence on the cellular interface that enables an MS to retrieve information quickly and develop a sleep mode. The mobile phone only needs to wake up at predefined instances to receive messaging. A superframe is made up of sixteen sequential frames, and a hyperframe is made up of a primary and secondary superframe. Since only slots 1 and 4 on each frame are assigned to DCCH, superframe creates a sequence of thirty-two bursts, or superframe phases (SFP), designated for either broadcast, paging, short message service, or access response information (see Figure 5). The superframe structures are flexible and broadcast to the MS when a DCCH is first acquired.

Call Operations

In PCS networks, the MS must register with the network during the initial daily power-up. Registration is accomplished by identifying the MS via a radio transmission on the reverse DCCH. Registration messages are sent from the MS to the BS on the RACH. Once the MS is authenticated, the acceptance message is returned from the BS to the MS on the ARCH. The authentication process involves encryption techniques. A random challenge number is transmitted from the BS to the MS. The MS performs a calculation using the challenge number with an internal secret number (shared secret data, part A [SSD-A]), then returns the result to BS. The SSD-A is derived from a second internal number (A-Key), which is preset at the factory or entered by the user via keyboard of the mobile set. If the BS suspects that the SSD-A has been compromised, the BS can change SSD-A via DCCH to a new value, and only the BS has knowledge of the proper A-Key value for these operations.

A call from the MS begins with an access to the BS on DCCH. The BS verifies several parameters and ensures the availability of resources for the call before selecting an idle DTC. The BS also synchronizes each MS with a master clock when a service is initiated. An MS being called is more complicated because it must first be paged

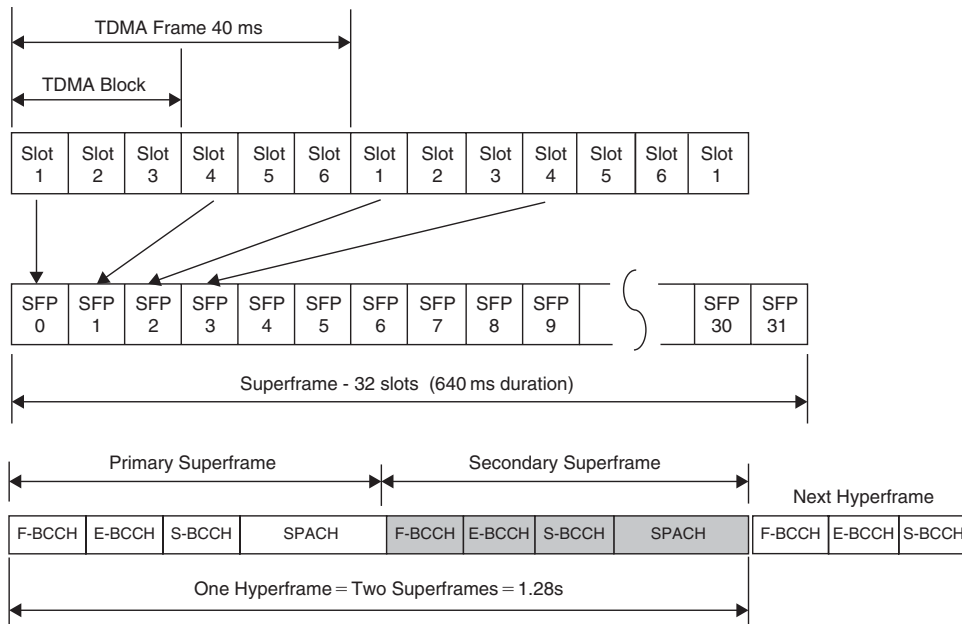

Figure 5: IS-136 frame, superframe, and hyperframe structure

before responding. In this event, the BS in the last known location area must page the MS. The MS may “sleep” in a low-powered state until a paging window appears, to conserve the battery charge. Following the receipt of a paging message, the MS must make radio access to the BS, where an exchange of messages via DCCH leads the MS to the correct DTC.

Mobile assisted handoff (MAHO) is a system in which the MS assists in the handoff decisions. IS-136 uses two types of channel quality information to determine handoff: signal strength of neighbor channels and an estimated bit error rate of the current channel. MS participation allows for reverse channel measurements that are not capable from the BS. The BS sends the MS a MAHO message containing a list of channels from up to twenty-four neighbor cells. During idle time slots, the MS measures the signal strength of these channels and continuously sends a channel strength report back to the BS. Since adjacent cells are approximately the same size, transmission delay and time adjustment can usually be avoided; a seamless handoff can typically be accomplished without losing coded speech. In reality, there is a brief interruption of the coded speech data in order to process handoff, about 0.2 s, but the missing data is interpolated by the speech coder.

THE OTHER 2G TDMA STANDARDS

2G technologies can be categorized into TDMA- and CDMA-based standards depending on the type of multiplexing used. In addition to IS-136, the main TDMA-based 2G standards are:

- GSM: originally from Europe but used worldwide
- PDC: used exclusively in Japan
- iDEN: used exclusively by Nextel in the United States

The GSM Standard

The GSM standard does not support dual-mode handset and backward compatibility. As a result, GSM has a much simpler design. Predating PCS in the United States, GSM has a version—digital cellular system 1800 (DCS 1800)—that operates at 1800 MHz, which uses less power and has greater capacity because more frequencies are available. Similar to IS-136, GSM uses a mix of FDMA and TDMA. Instead of 30 KHz, GSM divides frequency to 200 KHz channel spacing, forming 124 carriers in GSM 900 and 374 carriers in DCS 1800. Each carrier frequency is then further divided into eight slots using TDMA, with each burst lasting 0.58 ms and carrying 114 data bits, forming a 4.6ms frame with a 270 kbps gross bit rate per channel (ETSI 1989).

GSM uses Gaussian minimum shift keying (GMSK) for signal modulation. GMSK is a continuous phase modulation scheme with a constant envelope and narrow band. GMSK avoids linearity and frequency amplification requirements common in linear modulation schemes, such as $\text{Pi}/4$ DQPSK in IS-136. However, the DQPSK carries two bits in a symbol, making it twice as efficient as GMSK. Nevertheless, lower power efficiency in IS-136 is an important issue for mobile device regarding battery life. The GSM speech coder is based on the residually excited linear predictive (RELPE) scheme, which is enhanced by including a long-term predictor. The coder provides 260 bits for a 20 ms block of speech at 13 kbps. Although the ACELP coder in IS-136 has better speech quality, RELPE operates at a lower speech rate and has a lower delay (Garg and Sneed 1997).

Similar to IS-136, GSM has two types of channels: traffic channels (TCH) that transport speech and data, and control channels (CCH) that manage and administrate. Slot format for TCH is identical forward or reverse, and the time difference between transmit and receive must be

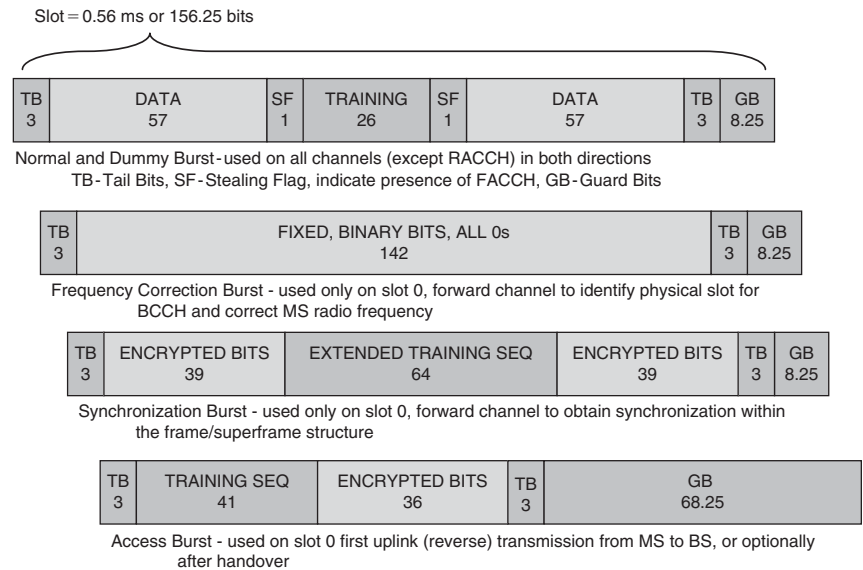

Figure 6: GSM channel structure

three time slots, which greatly simplifies its transceiver. GSM also uses frequency hopping to reduce the effects of co-channel interference, multipath, and fading. TCH are organized into a twenty-six-frame multiframe, with twenty-four used for traffic, one for SACCH, and one in reserve, with duration of exactly 120 ms (see Figure 6; numerical values refer to bits). Definitions of subchannels are as follows:

- Tail bits: used to help equalize data bits toward either end of the data stream
- Stealing flag: used to indicate a stolen data stream for control information
- Training sequence: used for equalization; eight different training sequences are used with low mutual cross-correlation, and the operator assigns a different one to neighboring cells for identification purposes
- Guard bits: bits between each time slot that keep data bursts separated

GSM logical channel definitions are as follows:

- Broadcast control channel (BCCH): continuous broadcasting to the MS
- Frequency correction channel (FCCH): used by the MS to synchronize the carrier
- Synchronization channel (SCH): used by the MS to synchronize time slot structure
- Paging channel (PCH): alerts the MS of incoming call
- Random access channel (RACH): SDCCH allocation requests from the MS
- Access grant channel (AGCH): allocates an SDCCH to the MS upon a RACH request
- Stand-alone dedicated control channel (SDCCH): negotiates services requested
- Fast associated control channel (FACCH): handover and frequency reassignments

There are four different types of transmission bursts in GSM: the normal burst, F burst for FCCH, S burst for SCH, and access burst for RACH. F burst and S burst have the same length but different structures than a normal burst. Access burst is shorter than the normal burst, with only seventy-seven data bits. The broadcast and common control channels are used for synchronization, exchange of system information, and setting up calls. These channels occupy slot 0 in a frame and cycle through every fifty-one frame times. If more control capacity is needed, slots 2, 4, and 6 can be used in the same carrier. Similar to the IS-136 hyperframe, GSM also organizes in multi-frame structures. TCH and SACCHs are grouped into a twenty-six-frame multiframe, and CCHs are defined as a fifty-one-frame multiframe structure with duration of approximately 235 ms. The fifty-one frames are grouped into five sets of ten frames each, with one idle frame. Each set starts with a FCCH followed by a SCH. The remaining eight frames form two block of four. The first block of the first set is for BCCH, and the remaining nine blocks are for PCH and AGCH.

The steps involved in setting up calls are similar in all PCS systems. However, in IS-54/136, there was no original plan regarding mobile network switching; specific features are designed and added as required. In contrast, GSM was designed from the beginning with all of its network features prespecified.

The PDC Standard

PDC is a 2G cellular standard used exclusively in Japan; it is implemented in the 800 and 1500 MHz frequency bands. PDC uses a 25 KHz carrier with a variation of TDMA to implement three time slots, Pi/4-DQPSK modulation, achieving a bit rate of 11.2 kbps (ARIB 2003). PDC is the most spectrally efficient of the TDMA technologies, with six half-rate (or three full-rate) slots possible in a 25 KHz channel spacing, compared to three in 30 KHz for IS-136 and eight in 200 KHz for GSM. PDC has weak

broadcast strength; this standard allows small, portable phones with light batteries at the expense of substandard voice quality. PDC also has problems maintaining the connection, particularly in enclosed spaces like elevators.

Along with the other cellular wireless standards, PDC can be developed along a gradual evolutionary path to the IMT-2000 standard. Japan is actually the first country to introduce 3G on a large commercial scale. NTT DoCoMo, Japan's dominant cellular operator with 45.4 million total customers and a 56 percent market share, rolled out its universal mobile telephone service (UMTS) network in late 2001. Japan now has nearly 14 million 3G users, compared with just a few hundred thousand in European countries such as Britain and Italy. Surveys projected that about 40 percent of Japanese subscribers would use 3G-only networks by 2005, and that 2G, PDC included, would be phased out in Japan by 2006 (Kane 2004).

The iDEN Standard

iDEN is another 2G wireless standard that uses TDMA, dividing the 25 KHz channel spacing into six 15 ms time slots. iDEN operates in 800, 900, and 1500 MHz bands and is based on GSM architecture. iDEN uses VSELP coders for voice compression and quadrature amplitude modulation (QAM) to deliver a 64 kbps data rate. QAM was chosen, in part, because it does not require adaptive equalization or other relatively expensive methods to correct for transmission path delays and rapidly changing signal strength that are common in mobile radio environments.

iDEN is a high-capacity digital trunked radio system. Conventional trunking systems define a control or traffic channel by specifying a set of inbound and outbound frequencies to a user. In iDEN, a single inbound/outbound frequency pair is shared among six users through TDMA. Each user transmits and receives only during its assigned time slot, such that the transmission from any given MS is a pulsed signal with a 1/6 duty cycle. The BS is able to transmit and receive during any of the six time slots. Each MS is assigned a unique channel designation, which is defined by a carrier number, which specifies the inbound/outbound frequency pair and a time-slot definition.

iDEN is a proprietary Motorola technology. Only Motorola makes iDEN phones, and only Motorola makes iDEN infrastructure equipment (Motorola 2000). Nextel is the largest U.S. operator of iDEN services. To provide high data rates for packet data, Nextel started to develop a 2.5G technology called WiDEN, but it is a technology with no clear path for 3G migration. Although Nextel has stated they will support iDEN through 2010, their merger with Sprint, which uses CDMA, has cast serious doubt over iDEN's future (Ankeny 2005).

TDMA AND THE MARCH TO 3G

As mobile application migrates from voice to data, technology for "continuous" packet switching is critical for 3G development. Currently, there are two 2.5G standards: general packet radio services (GPRS) for IS-136 and GSM, and CDMA/IS-95. GPRS enhances GSM by overlaying packet-switching architecture onto the current circuit-switched framework, while infrastructures such as

channel structure and radio interface are preserved. Data is transmitted in the same 0.58ms burst, and modulation and encoding remain the same. Four consecutive GSM frames are aggregated to allow for higher-speed packet data transfers. In theory, GPRS enables mobile devices to connect to the Internet via a packet-switching network at speeds up to 171.2 kbps using eight time slots simultaneously (Buckingham 2000). GPRS also has a version for IS-136 that is structured similarly by aggregating IS-136 frames. However, the technology has not been widely adopted (Balachandran et al. 1999).

GPRS is considered the first step in the transition to 3G, positioned to be complementary to enhanced data rate for global evolution (EDGE). EDGE enhances the radio interface to GSM with 3*Pi/8 8-PSK modulation, enabling three bits per symbol. However, 8-PSK is more susceptible to noise and attenuation. Using eight time slots and a better filtering design, a data rate of 473.6 kbps can be acquired. EDGE and GSM signals can be transmitted on the same frequency, occupying different time slots, and both can use existing GSM equipment.

There are several competing 3G standards: UMTS as an upgrade for GSM, CDMA2000 as an upgrade for IS-95 PCS CDMA, and time-division synchronous code division multiple access (TD-SCDMA), as proposed in China (Chen, Fan, and Lu 2002). The ITU arbitrates between competing standards. It has developed a series of recommendations that define the key characteristics, which envision a worldwide common 3G interface and network. Although it does not dictate a channel or spectrum standard, ITU specifies that 3G should deliver data rates of 144 kbps in a mobile environment, 384 kbps in a pedestrian environment, and 2 Mbps in a fixed environment; both UMTS and CDMA2000 can meet these criteria (Passerini 2003).

UMTS requires paired 5 MHz frequency channels, four times as wide as the paired 1.25 MHz channels required for CDMA2000; thus, UMTS is also known as wideband CDMA (W-CDMA). It uses a combination of TDMA and CDMA technology. Similar to CDMA2000, UMTS uses variable-length spreading code with puncturing (Stallings 2002). Time-slot aggregation is also used with each frame 10 ms long, divided into sixteen time slots. By migrating to UMTS, operators will gain access to additional spectrums as well as greater capacity and expanded functionality of the new technology. Unfortunately, UMTS is currently deployed using the 1900 and 2100 MHz frequency band, and the 3G frequency auction in the United States is not scheduled until June 2006 (TechWeb 2004).

CONCLUSION

The standard 3G migration path for GSM is anticipated initially through GPRS and then UMTS. Operators may or may not deploy EDGE as an intermediary step. With regard to CDMA, whether using 800 MHz, 1900 MHz, or both, one can evolve to CDMA2000 using the current spectrum; all CDMA2000 handsets will be backward compatible. Although 3G migration path for GSM and CDMA operators are clear, the path is less certain for IS-136 because AT&T abandoned it in favor of GSM in November 2000. Currently, in the United States, Cingular/AT&T and T-Mobile use GSM/GPRS; Verizon and Sprint use CDMA.

Although CDMA offers better performance than GSM, there are 1.4 billion GSM subscribers—or 75 percent of cellular phone users—worldwide. With massive research and development efforts devoted to the GSM transition path and the expected economies of manufacturing scale over time, this premise alone may be a strong rationale for IS-136 operators to choose the GSM migration path.

The argument over whether CDMA or TDMA is a better technology may not be relevant. Similar to FDMA incorporating with TDMA in the IS-136 standard, newer technologies, like W-CDMA, will use CDMA, TDMA, and FDMA together to create standards built for high-speed data. Likewise, the news of TDMA IS-136's demise may also be premature. Some industry estimates assert that TDMA subscribers numbered 150 million by 2005, and TDMA technology is expected to survive another ten years. Whereas some TDMA operators are taking advantage of the changing global dynamics to offer higher wireless data rates through a GSM/GPRS overlay, TDMA will continue to prove its worth by bringing to operators large revenue streams that are critical to the funding of 3G deployment (Pearson 2001).

GLOSSARY

Authentication: The process of determining whether someone or something is, in fact, who or what it is declared to be

Base station (BS): A station in the mobile service that houses the transceiver. It defines a cell and handles the radio links with the mobile station.

Digital signal processing (DSP): Various techniques for improving the accuracy and reliability of digital communications.

Digitization: The process of converting information into a digital format, in which information is organized into discrete units of data called *bits*.

Encoding: The process of putting a sequence of characters into a specialized format for efficient transmission or storage. Decoding is the opposite process of converting an encoded format back into the original characters.

Encryption: The conversion of data into a form that cannot be easily understood by unauthorized people. *Decryption* is the process of converting encrypted data back into its original or clear form.

Frame: A complete unit of data transmitted between network points, usually containing a header and a trailer field that “frame” the data.

Handoff: In a mobile network, the radio links required are not permanently allocated for the duration of a call. Handoff is the switching of an ongoing call to a different channel or cell.

Mobile station (MS): A station in the mobile service intended to be used while in motion or during halts at unspecified points.

Modulation: The process of adding information to an electronic or optical signal carrier so that it can be sent over long distances.

Sleep mode: An energy-saving mode of operation in which all unnecessary components are shut down; common in many battery-operated devices.

Speech coder: A device that compresses digital representations of speech signals for the purpose of efficient transmission or storage.

INTRODUCTION

Based on the characteristics of the physical layer and the communication medium, computer networks can be divided into two types: point-to-point connections and broadcast. In a broadcast network, *terminals* or *nodes*, share a common medium or channel. A key issue in such a network is *collision*, which results from two or more nodes sending packets at the same time in the common channel. The process of determining which node has the right to transmit in the channel at a given time is called *medium* (or *multiple*) *access control* (MAC). Therefore, the major task of MAC protocols is to avoid collisions so that nodes can efficiently share the channel. The MAC layer is normally considered as a sublayer of the data-link layer in the network protocol stack. A MAC or link layer packet is also referred to as a *frame*. Thus, we will use both these terms interchangeably throughout this chapter.

A common approach to collision avoidance is to divide the common channel into multiple distinct subchannels and assign or schedule interfering nodes to different subchannels. We refer to protocols using this approach as *scheduled protocols*. They are also referred to as *allocation-based protocols* in the literature. Common examples include *time division multiple access* (TDMA), frequency division multiple access, and code division multiple access, which divide the channel by time, frequency, and orthogonal codes, respectively. These protocols are widely used in cellular communication systems (Rappaport 1996). For example, in traditional TDMA, time is divided into frames, and each frame consists of a fixed number of slots. Each slot is assigned to a node, so that different nodes transmit at different time slots. Such a fixed pre-allocation scheme is efficient in channel utilization when all nodes have packets to send. However, it becomes wasteful when only a few nodes actually have data. To improve channel utilization in such cases, advanced schemes are required to dynamically allocate slots.

Another class of MAC protocols is based on *contention*. Rather than pre-allocating transmissions, nodes compete for a single and shared channel, thereby resulting in probabilistic coordination. Collision may happen during the contention procedure in such systems. The first class

of contention-based MAC protocols is ALOHA (Abramson 1970, 1985), which has two basic variants: pure ALOHA and slotted ALOHA. In pure ALOHA (Abramson 1970), a node simply transmits a packet when the packet is generated. Packets that collide are discarded and would be retransmitted later. Pure ALOHA has a low throughput because nodes essentially make no effort to avoid collision when they initiate new transmissions. Slotted ALOHA improves the throughput by dividing time into slots and only allowing new transmissions at the beginning of each slot. The duration of each slot is exactly the packet transmission time, assuming all packets have the same length. Collision probability is reduced because new packets generated in the current slot will be transmitted in the next slot and thus will not collide with an ongoing transmission in the current slot.

Carrier sense multiple access (CSMA) (Kleinrock and Tobagi 1975) is another family of contention-based protocols. The basic idea of CSMA is listening before transmitting. The purpose of listening is to detect whether the medium is busy, an ability also known as *carrier sense*. Before a node starts a new transmission, it listens to the channel to detect possible ongoing transmissions. If a busy channel is detected, then the node delays channel access (also known as *backoff*) for a random duration, after which it again repeats the above procedure. However, if the channel is idle, the node then transmits the packet. Because of this conservative collision avoidance procedure, CSMA is able to achieve much better throughput than ALOHA. In the next section we will discuss several basic CSMA protocols and give detailed performance comparison with ALOHA protocols.

Today, CSMA is one of the most widely used MAC protocols in modern computer networks, and significant improvements have been made to make CSMA more efficient and robust. The first example is Ethernet (IEEE Computer Society 2000). Almost all desktop and laptop computers are equipped with Ethernet today. The first improvement that Ethernet made to CSMA was collision detection, allowing nodes to quickly discover collisions while transmitting. To reduce the probability of persistent collisions, Ethernet also introduced the binary exponential backoff algorithm that dynamically increases the backoff

window size on repeated collisions. We will discuss these improvements below under “CSMA in Ethernet.”

CSMA is also the most popular medium access mechanism employed in wireless networks. Similar to Ethernet, WiFi or IEEE 802.11 (IEEE Computer Society 1999) devices can be seen on almost every laptop or handheld computer. Because of the complexity of wireless communication, more enhancements have been made beyond Ethernet. For example, as we will discuss in the section titled “Radio Communication and Related Issues,” the hidden terminal problem is a major issue in wireless networks. In IEEE 802.11, the collision avoidance technique is developed to handle the hidden terminal problem. In “CSMA Enhancements for Wireless Networks,” we will discuss major CSMA enhancements for wireless networks.

Recently, CSMA has gained strong attention in wireless sensor networks. A *sensor network* is a network of embedded computers equipped with sensors and short-range radios. There are numerous potential applications for sensor networks, such as habitat monitoring, distributed tracking, and smart space. Most sensor nodes operate on batteries, so energy becomes a critical resource for these nodes. CSMA is widely used in sensor networks mainly because of its flexibility and robustness to node density and topology changes. However, pure CSMA-based protocols are not energy efficient. For example, they require nodes to always listen to the channel, which is intensely energy-consuming. A lot of recent work has focused on improving the energy efficiency in CSMA protocols. We will discuss these new techniques as well as other CSMA improvement in the section titled “CSMA in Sensor Networks.”

BASIC CSMA PROTOCOLS

This section describes several basic CSMA protocols that were first presented by Kleinrock and Tobagi (1975). These protocols help us understand the basic concepts in CSMA and constitute the foundation of various advanced CSMA protocols that are widely used in practical data networks today.

These basic CSMA protocols were developed for the packet radio system. The radio channel is shared by a group of nodes, where all of them can hear each other. When a node starts transmitting, another node is able to detect the carrier after the signal propagates from the sender to the receiver. Assume the propagation delay, denoted by τ , is miniscule compared to the packet transmission time.

The first basic CSMA, called *nonpersistent CSMA*, works as follows:

1. Sense the carrier.
2. If the channel is idle, transmit the packet immediately.
3. If the channel is busy, reschedule transmission at a later time according to a randomly distributed delay function.

When scheduled retransmission time arrives, the node repeats the above process.

Compared to the nonpersistent CSMA, another variant named *1-persistent CSMA* is more aggressive in transmission. It works as follows:

1. Sense the carrier.
2. If the channel is idle, transmit the packet immediately.
3. If the channel is busy, wait and monitor the channel until it becomes idle, and then transmit the packet (with probability 1).

Because of the aggressive retransmission scheme, a collision will occur with probability 1 when two or more nodes have packets to send at the end of the current transmission.

A more general scheme is to replace the retransmission probability one with a parameter p , therefore named as *p-persistent CSMA*, via the following process:

1. Sense the carrier.
2. If the channel is idle, transmit the packet with probability p , or delay for τ seconds (the propagation delay) with probability $1 - p$. If the packet is delayed, repeat from step 1 at the end of the delay.
3. If the channel is busy, reschedule transmission to a later time according to a randomly distributed delay function.

We can see that all the above CSMA protocols require that a node first performs carrier sense when starting a new transmission. They differ in how they act after the channel is detected idle or busy. When we describe the above protocols, we assume that a node can start the CSMA process at any time. There is also a “slotted” version of these protocols in which the time axis is divided into slots with the size of τ seconds for each slot. In the slotted CSMA, all nodes are synchronized and are forced to start their CSMA process at the beginning of a slot.

To gain a better understanding of these basic CSMA approaches, we next present some performance comparison of the above protocols and the ALOHA protocol. These results were obtained by Kleinrock and Tobagi (1975). For detailed performance analysis, readers are referred to that paper.

The following assumptions are made to simplify analysis. There is no channel noise and all corrupted packets are the result of collisions. All packets are of constant length, and the packet transmission time is T . The propagation delay τ is identical for all transmitter-receiver pairs, and τ is much smaller than T . The ratio of τ and T is denoted by $a = \tau/T$. In slotted ALOHA, the slot size is T , whereas in slotted CSMA, the slot size is τ . The time needed for the node to detect the carrier is negligible. The network traffic consists of an infinite number of nodes that collectively form an independent Poisson source.

We are primarily interested in the *throughput*, which measures how many data units (bits or packets) can be transmitted in a unit time. If we can magically schedule all transmissions with no gaps and collisions, then the channel will be fully utilized and the throughput (in terms of bits per second) will be the same as the channel bandwidth. The realized throughput normalized to the channel

Figure 1: Channel utilization of ALOHA and basic CSMA protocols when the propagation delay is extremely small ($a = 0.01$) (Kleinrock and Tobagi 1975)

bandwidth is called *channel utilization*. The throughput usually changes as the offered load changes. The maximum achievable throughput of a MAC protocol is called the *capacity* of the channel under that protocol.

Figure 1 shows the channel utilization, or normalized throughput, of the ALOHA and basic CSMA protocols, with the varying offered traffic load when $a = 0.01$. We can see that the pure ALOHA has the lowest channel utilization because of its most aggressive transmission scheme. Slotted ALOHA is better than the pure ALOHA because it reduces the vulnerable interval (i.e., the maximum interval that two packets can overlap) from $2T$ to T . CSMA protocols are in general much better than ALOHA. The conservative approach of listening before transmitting is able to avoid many possible collisions. Finally, as a quantitative comparison, let us look at the maximum channel utilization—that is, the capacity of each protocol. Among the basic CSMA protocols, the slotted non-persistent CSMA achieves the highest capacity of 0.857. In comparison, the pure and slotted ALOHA can only achieve the capacities of 0.184 and 0.368, respectively.

It should be noted that the above results are obtained when the propagation delay is extremely small—that is, $a = \tau/T = 0.01$. The performance of CSMA protocols will decrease when the propagation delay increases because it takes a longer time (τ) to perform carrier sense. When

$\tau = T$, even the pure ALOHA achieves higher capacity than the nonpersistent CSMA. For a detailed comparison, the readers can refer to Kleinrock and Tobagi (1975).

CSMA IN ETHERNET

Ethernet is the most widely used *local area network* (LAN) technology today. It was developed by Xerox's Palo Alto Research Center and standardized by the Institute of Electrical and Electronics Engineers (IEEE) through its 802.3 standard (IEEE Computer Society 2000). Ethernet employs an extended version of the CSMA protocol, named *CSMA with collision detection* (CSMA/CD).

The original Ethernet (Metcalfe and Boggs 1976) uses a coaxial cable to connect all computers, as shown in Figure 2. It forms a *bus topology* in which all nodes (computers) directly share the same transmission cable or medium. Any packet that is sent by one node can be received by all nodes on the network. In other words, the transmission medium is a broadcast or shared medium.

Another type of Ethernet connection uses unshielded twisted pair cables with hubs or switches. This Ethernet implementation is most widely used today. In such a case, the hubs or switches form a *tree topology* in which computers are attached at the leaves of the tree. With the help of hubs or switches, computers attached to the network

Figure 2: An Ethernet uses a coaxial cable to connect all computers

can still directly talk to each other. For example, hubs retransmit received packets to all of the attached ports so that any packet will propagate to the whole network.

Collision Detection

As described in the previous section, collision happens in the shared medium when two or more nodes transmit at the same time. In Ethernet, transmitting a packet will generate a current in the cable with a modulated signal that reflects the bits in the packet. When two nodes transmit simultaneously, they drive the cable in different ways, resulting in a mixed signal that is indistinguishable.

Ethernet employs CSMA as its basic MAC protocol and adds the enhancement on collision detection. CSMA requires nodes to listen before transmit. The process of listening detects whether there is a signal (carrier) in the cable (medium) and is therefore called *carrier sense*. When the carrier is detected, a node defers its transmission until the medium becomes idle.

Although the basic CSMA avoids many collisions, it is not able to eliminate all of them. Figure 3 shows an example of collision between nodes A and C. In the example, both nodes started carrier sense at about the same time. However, node A finished its carrier sense a little earlier than C, and it started transmitting because the channel was idle. As a result of the propagation delay, it takes a little time for A's signal to reach C. Unfortunately, just before A's signal reaches C, C has finished its carrier sense and started sending its own packet. Therefore, collision occurs when two nodes happen to start their transmission at about the same time—that is, the difference of their transmission start times is smaller than the propagation delay between the two nodes.

In Ethernet, it is possible for a node—for example, node A in Figure 3—to detect the collision while it is transmitting. To do so, a node needs to listen to the medium while transmitting. It compares what it sends to what it receives. If the two versions do not match, then collision is detected. Figure 3 shows that node A potentially has to wait for the round-trip time between A and C before it can detect the collision. To reliably detect collisions, Ethernet requires a minimum packet length that has a transmission time that corresponds to the round-trip time between two nodes with the largest allowed distance on the network. When a node detects a collision, it does not terminate its transmission immediately. Instead, it keeps sending additional bits as a jam signal, allowing all transmitting nodes to detect the collision. When all nodes detect the collision, they can prepare for the next round of contention by adjusting their backoff time, as detailed in the next section.

Binary Exponential Backoff

Now we describe the complete CSMA/CD procedure for a node to transmit a packet on Ethernet. All nodes on the Ethernet keep monitoring the physical medium for traffic. They cannot transmit when the medium is busy. When the medium becomes idle, nodes continue to defer for a proper interframe (interpacket) space. The deferral is performed by using a timer.

When a node initiates a new transmission, it checks the current carrier sense result and the deferral timer. If the medium is idle and the deferral timer is not started, the node will send immediately. If the medium is busy or the deferral timer is started, the node defers its transmission. It will send when the deferral timer fires. During transmission, it performs collision detection. If collision occurs, it will try to resend the packet after a backoff period.

The length of the backoff period increases as the number of retransmission attempts increases according to an algorithm called *binary exponential backoff* (BEB). BEB was first described by Metcalfe and Boggs (1976) and later standardized by IEEE 802.3 (IEEE Computer Society 2000). Let us consider the n th retransmission attempt. First, a backoff window is determined as 2^k , where $k = \min(n, 10)$. The backoff window consists of 2^k time slots. Then a time slot r is chosen as a uniformly distributed random integer within $(0, 2^k)$. The actual backoff time is $r \times \text{slotTime}$, where *slotTime* is the duration of each slot. The value of n starts with a minimum number. Every time the transmission attempt fails, the node increments n by 1, which effectively doubles the backoff window. Therefore, the backoff window size will exponentially increase on repeated collisions until n reaches 10. The backoff algorithm effectively avoids persistent collisions on retransmissions. However, because it gives higher priority to new transmissions than retries, fairness may become an issue in some applications.

In summary, Ethernet is the most widely used LAN technology. It employs CSMA/CD as its basic MAC protocol. The major extensions of CSMA/CD to the basic CSMA are the collision detection and binary exponential backoff. Although the importance of CSMA is first exemplified by the widely adopted Ethernet technology, the collision problem is largely reduced in the later Ethernet that utilizes switches. Compared to hubs, a switch “learns” about destination hosts from the packets it relays and thus can reduce the range of flooding. In contrast to wired networks, research on CSMA has been significantly boosted in wireless networks, largely because of the complexity of the wireless medium. We next review CSMA in wireless networks.

Figure 3: A collision example on Ethernet; node A sends first, but node C starts sending before it detects A's transmission

CSMA IN WIRELESS NETWORKS

Wireless networking is widely used today, mainly because of its easy deployment and convenient mobility. Popular examples include WiFi, Bluetooth, and ZigBee networks. A WiFi network is also known as a *wireless local area network*, standardized as IEEE 802.11 (IEEE Computer Society 1999). Bluetooth is designed for wireless personal area networks, and its specification is the foundation of the IEEE 802.15.1 standard (Bluetooth, undated; IEEE Computer Society 2002). ZigBee mainly targets low-rate, low-power sensor networks, and its MAC and physical layer are standardized in IEEE 802.15.4 (ZigBee Alliance, undated; IEEE Computer Society 2003). Many wireless networks adopt CSMA as their basic MAC protocol. However, different extensions have been proposed to enhance the basic CSMA protocol. Before we describe these extensions, we first look at the characteristics of radio communication and related issues to MAC protocols.

Radio Communication and Related Issues

Wireless networks have some characteristics that are different than wired networks. Understanding these characteristics helps us understand various enhancements to the basic CSMA for wireless networks. First, radio devices normally work in the half-duplex mode because the transmitter and receiver share the same radio frequency front end. If a radio turns on both of its transmitter and receiver, what enters the receiver is the signal from its own transmitter. For this reason, the transmitter and receiver do not work at the same time. When a radio is turned into transmit mode, it is not able to receive signals from other nodes. As a result, a normal radio does not have the collision detection capability as the node in Ethernet.

The second characteristic of wireless networks is that each node only has a limited transmission range. In Ethernet, packets can reach the whole network either directly or with the help of repeaters, hubs, or switches. The actual transmission range of a radio is determined by its transmission power, channel noise, and interference level as well as by the receiver's sensitivity. The limited radio range implies that CSMA will fail if two nodes cannot hear each other.

Third, collisions happen on receivers when two or more packets with comparable strength arrive at the receiver simultaneously. In this case, the receiver is not able to correctly receive any of these packets. It may completely miss both packets or receive one with errors. If two nodes cannot directly hear each other, then their concurrent transmissions may still cause collisions on some nodes that can hear both of them. Another implication is that collision depends not only on when the two nodes transmit but also on their propagation delays to reach a receiver. A third factor is the signal strength. If two packets arrive at the receiver with largely different strengths, they may not necessarily cause collision. The stronger signal can *capture* the receiver and make it treat the weaker signal as noise. The effect of channel capturing by strong signals may affect the performance of CSMA protocols (Ware et al. 2000) but can also be exploited to reduce collisions (Nadeem 2005; Whitehouse et al. 2005).

Finally, the link quality (in terms of packet error rate) varies largely between nodes at different distances and actual locations (Woo, Tong, and Culler 2003). In general, link quality decreases as the distance between nodes increases. However, there is a large area after a certain distance that a receiver cannot reliably receive packets from a transmitter, but the transmitter's signal is strong enough to collide with other transmissions. This area is known as the *gray area* (Zhao and Govindan 2003) primarily because of multipath effects and interfering signals. The gray area indicates that the radio's interference range can be much larger than the actual packet reception range.

The above characteristics imply that CSMA faces more challenges in wireless networks than in wired networks. A major problem in wireless networks is the *hidden terminal* problem (Tobagi and Kleinrock 1975), which arises in multihop networks. Figure 4 illustrates the problem on a two-hop network with three nodes. Suppose nodes A, B, and C can only hear from their immediate neighbors. When node A is sending to B, node C is not aware of this transmission, even if it keeps listening to the channel. Because its carrier sense still indicates that the medium is idle, node C can start transmitting now. Unfortunately, such transmission will collide with A's transmission at the receiving node B. Node A and C are said to be *hidden* to each other; their concurrent transmissions will cause collisions at nodes that can hear both of them. The basic CSMA is not capable of solving the hidden terminal problem because each node only has limited transmission range.

Another related problem is called the *exposed terminal* problem, as shown in Figure 5. In the example, node B

Figure 4: The hidden terminal problem: nodes A and C are hidden to each other. Dotted circles represent their transmission range. When they send at the same time, their packets collide at node B.

Figure 5: The exposed terminal problem. When node B sends to node A, C is exposed to the transmission. C's carrier sense does not allow it to send to D, even though such transmission does not interfere with A's reception.

is sending data to A. Again, we assume that each node can only hear its immediate neighbors. During B's transmission, node C's carrier sense will always detect a busy medium. Therefore, node C is said to be *exposed* to B's transmission, and it cannot send any packets because of the busy medium. However, if we look at node D, it is an immediate neighbor of node C but cannot hear node B. In this case, node C is actually able to send packets to D because C's transmission can be correctly received by D. More important, C's transmission will not interfere with B's current transmission because node A is too far to receive C's packets. The major problem of the exposed terminal is not collision, but reduced channel utilization.

Note that in Figures 4 and 5 we have adopted an idealized propagation model, which represents the transmission range as a circle. If a node is within the circle, it is able to receive all or most packets from the sender. If a node is outside the circle, it basically cannot receive anything. In reality, the radio propagation is much more complicated, and the transmission range is largely irregular. Moreover, the interference range is much larger than the range that packets can be correctly received (Zhao and Govindan 2003). As a result, two-hop neighbors, such as nodes A and C in Figure 5, may still have enough interference to each other when they transmit. Therefore, it is difficult to say whether node C can send during B's transmission in a real-world network. To be conservative, node C should keep silent. Another reason for node C not to send to D is that any reply message from D, such as an *acknowledgment* (ACK) message, will surely collide at node C with B's transmission. In brief, real-world protocols are less concerned about the exposed terminal problem but deal more with the hidden terminal problem.

CSMA Enhancements for Wireless Networks

This section describes some important enhancements to CSMA for wireless networks. The first one is *CSMA with collision avoidance* (CSMA/CA). Karn first described CSMA/CA to address the hidden terminal problem, and mentioned its use in the Apple LocalTalk network (Karn 1990). CSMA/CA was later adopted by the wireless LAN standard, IEEE 802.11 (IEEE Computer Society 1999). The basic mechanism in CSMA/CA is to establish a brief handshake between a sender and a receiver before the sender transmits data. The handshake starts from the sender by sending a short *request-to-send* (RTS) packet to the intended receiver. The receiver then replies with a *clear-to-send* (CTS) packet. The sender starts sending data after it receives the CTS packet. The purpose of RTS-CTS handshake is to announce the following transmission to the neighboring nodes so that they will delay their potential transmissions. In the example of Figure 4, although node C cannot hear the RTS from A, it can hear the CTS from B. If a node overhears an RTS or CTS destined to other nodes, it delays its own transmission. CSMA/CA does not completely eliminate the hidden terminal problem, but now the collisions are mainly on RTS/CTS packets. Because these packets are normally much shorter than data packets, the cost of collisions can be largely reduced.

In his paper, Karn also proposed an enhancement to CSMA/CA, naming his protocol *multiple access with collision avoidance* (MACA) (Karn 1990). MACA added a duration field in both RTS and CTS packets to indicate the duration of the following data transmission so that other nodes know how long they should back off.

Multiple access with collision avoidance for wireless (MACAW) (Bharghavan et al. 1994) proposed further improvements over MACA. It added an ACK packet after each data packet. If a sender fails to receive an ACK after sending data, it will restart the CSMA process and try to resend the data. The ACK-retry process allows rapid error recovery at the link layer. Otherwise, such recovery has to be handled by the transport or application layer, which can be much slower. MACAW also demonstrated the unfairness of the BEB algorithm using two nodes generating heavy traffic. It shows that eventually only one node transmits at the channel capacity, and the other one is completely backed off. A major reason is that nodes do not share the information about the current contention level. Another reason results from the rapid change of contention window size. To rectify this problem, MACAW proposes a scheme to exchange backoff counter values in transmitted packets, as well as a gentle window adjustment algorithm with *multiplicative increase and linear decrease* (MILD).

The wireless LAN standard, IEEE 802.11, has adopted most of these features in CSMA/CA, MACA, and MACAW (except backoff value exchange and MILD) in its *distributed coordination function* (DCF). The standard has also made various other enhancements, such as virtual carrier sense, binary exponential backoff, and fragmentation support (IEEE Computer Society 1999). Virtual carrier sense is also referred to as the *network allocation vector* (NAV) in the standard. The NAV is a timer that keeps track of current channel states according to the duration information in the RTS and CTS packets. Whenever a node receives a new RTS or CTS, if the duration value is larger than the NAV timer, the node updates the NAV timer to reflect the new state of channel usage. *Virtual carrier sense* means that a node checks the NAV value to determine if the medium is busy. The medium is determined as idle only when both virtual and physical carrier sense results indicate idle.

Figure 6 illustrates the basic DCF procedure in IEEE 802.11. When a node has a new packet to send, it performs both virtual and physical carrier sense. If the medium is busy, as shown in the figure, the node defers its access until the end of the transmission (suppose the node gets a correct packet) plus an additional time called *DCF interframe space* (DIFS). During the deferral, the node keeps monitoring the channel. If the channel is still idle at the end of the DIFS, the node starts a random backoff procedure by randomly selecting a time slot in the contention window. The same BEB algorithm in Ethernet (see "Binary Exponential Backoff") is adopted to adjust the contention window size, despite its well-known fairness issue (Bharghavan et al. 1994). During backoff, the node keeps sensing the channel. If the medium keeps idle until the end of the backoff time, the node starts transmitting. If the medium becomes busy at any time during the deferral and random backoff,

Figure 6: Packet transmission procedure in IEEE 802.11 DCF (DIFS = DCF interframe space)

the node suspends its backoff timer until the channel is sensed idle again.

DCF is the fundamental medium access method in IEEE 802.11, and it can be used with or without an access point. An ad hoc network (without access point) only runs DCF. An infrastructure network (with an access point) can optionally implement the *point coordination function* (PCF), which is a contention-free MAC with a polling mechanism that the access point uses to interrogate each node for possible transmissions. PCF and DCF normally coexist in an infrastructure network.

CSMA IN SENSOR NETWORKS

Sensor networks are a special class of wireless networks in which most nodes are equipped with embedded processors, short-range radios, and various sensors (Hill et al. 2000). A sensor network normally consists of a large number of such nodes that organize themselves into a multihop wireless network. The nodes collaborate to perform a common sensing and data-collection task. A major difference of a sensor network to a wireless LAN is that sensor nodes are highly resource constrained. They have extremely limited computing power, memory size, and energy source (usually batteries).

CSMA protocols are widely adopted in ad hoc and sensor networks, largely because of their robustness and flexibility to the changes of topology and node density. Various protocols have been proposed to improve the performance of CSMA used in traditional data networks. We next review these new approaches. We will start with energy efficiency, which is the most active area in recent CSMA research.

Improving Energy Efficiency

Traditional MAC protocols, including CSMA, usually focus on throughput or fairness. In sensor networks, energy is a critical resource, so improving energy efficiency in MAC protocols becomes a primary concern. The major reason is that the energy consumed in communication is usually much higher than that in computing. There are four major sources of energy waste in MAC protocols (Ye, Heidemann, and Estrin 2002): collision, control overhead, overhearing, and idle listening.

Collision wastes energy because all senders and the receiver spend energy on a corrupted, useless packet. *Control packets* are the overhead of energy consumption because they do not directly convey data. A third source

of energy waste is *overhearing* packets that are destined to other nodes. The basic approach to avoid overhearing is to put a node into sleep when its neighbors are transmitting unrelated packets. *Power-aware multiaccess protocol with signaling* (Singh and Raghavendra 1998) does this with a separate control channel. *Sensor-MAC* (S-MAC) (Ye, Heidemann, and Estrin 2002) achieves the same goal in a single channel by utilizing RTS and CTS packets. *Idle listening* is the last major source of energy waste. It happens when the radio is listening to the channel to receive possible data or monitoring the channel activity. Reducing idle listening has been a major research topic in recent CSMA-based protocols. The rest of this subsection is devoted to this important new CSMA improvement.

Most traditional CSMA protocols keep the radio in idle state to listen to the channel when a node has no data to send. In many short-range radios, idle state consumes about the same power as it is actually receiving data. For example, on the Mica2 Mote (Crossbow Technology, undated), the idle:receive:send ratios for radio power draw are 1:1:1.4. Idle listening can dominate the energy cost in networks with infrequent data transmission and long idle time.

The basic technique to reduce idle listening is to put the radio into low duty cycles. In doing so, a node sleeps for a relatively long time and only wakes up periodically to listen for possible traffic. As an example, the Chipcon radio used on a Mica2 Mote only consumes 3 μ W in sleep mode (Chipcon, undated), three orders of magnitude less than that in idle or receive mode. Low duty cycle MAC protocols can significantly reduce idle listening while still providing the abstraction that the network is always available. The major trade-off is to conserve energy at the cost of increased latency (or reduced throughput).

There are two major approaches for low duty cycle operations: scheduled and asynchronous listening. In the scheduled scheme, neighboring nodes exchange their sleep and listen schedules and try to maintain synchronization. An example is the IEEE 802.11 *power-save* (PS) mode, where nodes sleep if they have no data to send, but need to wake up periodically to receive beacons. Following each beacon, there is an *ad hoc traffic indication message* (ATIM) window in which all nodes remain awake. If a node has a packet to send, it first sends an ATIM packet to notify the receiver and then sends data. This PS mode is designed for a single-hop network in which all nodes can hear each other. Directly applying it to a multihop network may lead to problems such as clock synchronization, neighbor discovery, and network partitioning (Tseng, Hsu, and Hsieh 2002).

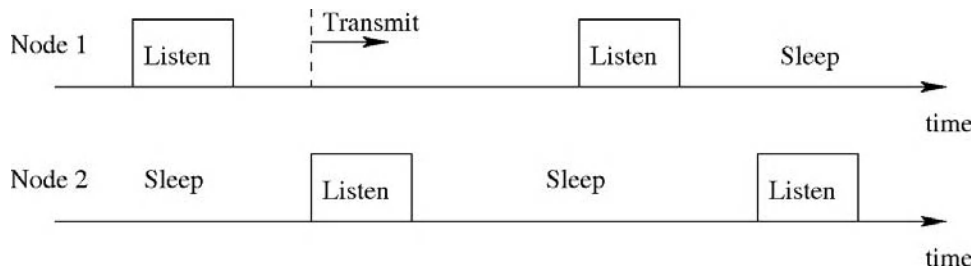

Figure 7: S-MAC allows multiple schedules for multihop networks

S-MAC is the first CSMA protocol with sleep and listen schedules designed for multihop sensor networks (Ye, Heidemann, and Estrin 2002; Ye, Heidemann, and Estrin 2004). S-MAC allows nodes to select different schedules but encourages them to follow a common one (possibly using the global schedule algorithm—see Li, Ye, and Heidemann 2005). Neighboring nodes share their schedule information, no matter whether they follow the same or a different schedule. Therefore, when a node has a packet to send, it is able to schedule its transmission at the exact moment when the receiver is listening, as shown in Figure 7. To keep schedule synchronization, each node periodically broadcasts its schedule as a synchronization (SYNC) packet. *Timeout MAC* (T-MAC) (Van Dam and Langendoen 2003) adopts the same scheduling mechanism but improves S-MAC by reducing the wakeup duration controlled by an adaptive timer.

The major advantage of scheduled listening is the efficient transmission. Its potential drawback is the overhead of schedule synchronization. However, as shown in Ye, Silva, and Heidemann (2006), such overhead can be especially small if optimal parameters are used.

In asynchronous MACs, nodes sleep and wake up on their own without explicit coordination. A promising asynchronous technique is *low-power listening* (LPL) presented in *WiseMAC* (El-Hoiydi et al. 2003) and *Berkeley media access control* (B-MAC) (Polastre, Hill, and Culler 2004). In LPL, nodes wake up briefly to check channel activity without actually receiving data. We call this action *channel sampling* or *channel polling*. If the channel is idle, the node immediately goes back to sleep. Otherwise it stays awake to receive data. Although nodes regularly poll the channel with a predefined polling period, they still wake up asynchronously. To wake up a receiver, a sender uses a long *preamble* (as long as the polling period) before each message, which is guaranteed to intersect with the receiver's polling time, as illustrated in Figure 8.

Figure 8: In LPL, nodes poll channel asynchronously. When transmitting, a node sends a long preamble to wake up the receiver(s).

Channel polling minimizes the cost on listening because checking channel activity uses the minimum time when a node is active. Compared to S-MAC and T-MAC, channel polling is more than ten times shorter than their listening windows. Therefore, LPL consumes much less energy than S-MAC or T-MAC in lightly loaded networks. However, with asynchronous wakeup, polling efficiency is gained at the much greater cost of transmissions. Such cost can become prohibitive for some event-triggered applications.

Several approaches have been proposed to improve LPL. *WiseMAC* (El-Hoiydi et al. 2003) can reduce the preamble length after an initial unicast packet with a long preamble. The receiver piggybacks its next polling time in the ACK packet, allowing the sender to send the next packet with a short preamble. A similar optimization is possible in B-MAC (Polastre, Hill, and Culler 2004) for messages consisting of a sequence of packets. *Uncertainty-driven B-MAC* (UB-MAC) (Ganeriwal et al. 2005) reduces the long preambles by precisely estimating the clock drift between packet transmissions. UB-MAC requires high-precision time synchronization, which is CPU intensive. *X-MAC* (Buettnner et al. 2006) embeds the destination address in the preamble, so that a node can quickly determine whether it is the intended receiver without waiting for the whole preamble. The receiver can further interrupt the sender's preamble transmission by sending back a brief ACK message. It should be noted that all the above improvement schemes are limited to unicast packets. Because nodes asynchronously poll the channel, broadcast packets have to use long preambles in order to be captured by all nodes.

Scheduled channel polling MAC (SCP-MAC) (Ye, Silva, and Heidemann 2006) takes a different approach by combining the strengths of scheduling and channel polling. SCP synchronizes the polling times of neighboring nodes, as shown in Figure 9. When sending data, a node

Figure 9: SCP-MAC synchronizes neighboring nodes on common schedules. When transmitting, a node sends a short tone to wake up the receiver(s).

first sends a short tone to wake up the receiver and then sends the data. The wakeup tone is much shorter than the LPL preamble, and the synchronized polling schedules enable the same efficient transmission for both broadcast and unicast packets. The major cost in SCP-MAC is maintaining schedule synchronization. However, by quantifying the cost and finding optimal parameters, SCP-MAC shows that such cost can be quite small. Analysis and experiments show that SCP-MAC can improve energy efficiency over LPL by a factor of 3 to 6 (Ye, Silva, and Heidemann 2006).

Other CSMA Improvements

In this subsection, we look at a few other schemes to improve CSMA for wireless sensor networks, the major goals of which do not include energy efficiency. These protocols focus on performance aspects such as latency, throughput, and fairness.

A side effect of the listen and sleep schedule introduced by S-MAC is the increased latency because a sender has to wait for a receiver's listening time. This delay is termed as the *sleep delay* (Ye, Heidemann, and Estrin 2004). There has been work on reducing multihop latency caused by the sleep delay. S-MAC uses RTS and CTS to inform the next-hop node of possible transmission, reducing latency at every two hops. T-MAC further adds future RTS packets so that data can keep moving over every three hops. D-MAC (Lu, Krishnamachari, and Raghavendra 2004) and the fast path algorithm (Li, Ye, and Heidemann 2005) try to explicitly stagger the wakeup times along a transmission path. They require the help from the routing layer to obtain path information. *Dynamic sensor MAC* (DS-MAC) (Lin, Qiao, and Wang 2004) doubles the duty cycle for reducing sleep-delay based on the queued data and average one-hop latency value computed by nodes. *Latency and energy aware MAC* (LE-MAC) (Suh, Shrestha, and Ko 2006) makes the RTS and CTS scheme used in S-MAC more effective over multiple hops by exploiting the longer physical carrier sense range for waking up relay nodes. SCP-MAC proposes adaptive channel polling, which dynamically increases the channel polling frequency of nodes driven by data traffic, and it requires no explicit signaling.

Woo and Culler proposed a MAC protocol for wireless sensor networks that combined CSMA with an adaptive rate-control mechanism (Woo and Culler 2001). Many sensor networks face the funneling problem, in which the nodes that are closer to the base station carry more traffic. The MAC protocol aims to fairly allocate bandwidth to all nodes in the network. Each node dynamically adjusts its rate of injecting its original packets to the network.

The paper also suggests the use of implicit ACKs to reduce control overhead. An *implicit ACK* is the same packet that a parent node rebroadcasts after it receives from its child. To capture the implicit ACK, the child node has to keep listening, which may be inefficient because of overhearing unrelated traffic.

Tay, Jamieson, and Balakrishnan (2004) studied how to minimize collision in a fixed contention window when there are a large number of contenders. In traditional slotted CSMA, a node randomly selects a slot with uniform distribution in the contention window to perform carrier sense. Tay, Jamieson, and Balakrishnan developed CSMA/ p^* , in which p^* is the optimal distribution that minimizes the collision probability given the fixed number of slots and the known number of contending nodes. The distribution p^* is nonuniform, which has extremely small values for the beginning slots and increases rapidly for the last few slots. Such a distribution is highly effective in selecting one transmitter among a large number of contenders. The authors also derive a distribution, named *Sift* (Tay, Jamieson, and Balakrishnan 2004; Jamieson, Balakrishnan, and Tay 2006), that approximates p^* without knowing the exact number of contenders.

Rhee et al. (2005) proposed a hybrid protocol to combine TDMA with CSMA, called *zebra MAC* (Z-MAC). Z-MAC assigns each node a slot, but other nodes can borrow the slot (with contention) if its owner has no data to send. Z-MAC takes advantages of both CSMA and TDMA according to the changes in traffic load. When traffic load is light, Z-MAC works like CSMA (based on B-MAC) because all nodes are allowed to access the slots whose owners do not have data. Z-MAC works like TDMA at heavy load because slot owners have higher priority than other nodes. Z-MAC significantly improves the throughput of B-MAC, but its energy efficiency remains similar to B-MAC. The major overhead of Z-MAC is the distributed slot assignment algorithm and potential periodic synchronization. Based on the same idea of combining TDMA with CSMA, the *funneling MAC* (Ahn et al. 2006) proposes to only apply the hybrid scheme around the sink, which is normally the most congested area. This scheme achieves better time synchronization than Z-MAC over long duration by adopting a centralized control on the sink node, therefore further improving performance.

CONCLUSION

In this chapter, we have reviewed CSMA protocols in modern computer networks. First, we have discussed ALOHA and basic variants of CSMA protocols. Using the conservative approach of listening before transmitting,

CSMA performs much better than ALOHA. Then we have discussed CSMA in Ethernet, which is the most widely used LAN technology today. The ability to detect collision and the use of binary exponential backoff helps CSMA maintain throughput with heavy traffic. CSMA has gained more attention with the widespread popularity of wireless technologies. We have discussed the complexity of wireless networking compared to Ethernet. Collision avoidance is the major enhancement to CSMA for the wireless LAN. Finally, CSMA has attracted strong attention in the new area of wireless sensor networks because of its robustness and flexibility. Various approaches have been proposed to improve the energy efficiency of CSMA protocols.

GLOSSARY

Backoff: The process of deferring access to the channel when a busy medium is detected.

Carrier Sense: The method that determines whether the medium is idle or busy. A busy medium indicates that a nearby node is transmitting.

Channel Polling (or Channel Sampling): The process a node uses to briefly turn on its radio to measure the channel activity.

Collision: When two concurrent transmissions corrupt each other; happens when two transmitted packets arrive at a receiver with overlapping durations and comparable signal strengths.

Contention: A probabilistic procedure that each node follows to access the shared medium.

Duty Cycle: The percentage of time that a node keeps its radio on. Nodes operate at low duty cycles to conserve energy.

Ethernet: A cable-connected LAN that is based on the shared medium and broadcasting. Ethernet is one of the most widely used LAN technologies.

Hidden Terminals: Refers to nodes that are outside the transmission range of each other but whose concurrent transmissions can collide on a receiver between them.

Idle Listening: Refers to the state that a node is listening to the channel in order to receive possible data.

Local Area Network (LAN): A computer network that spans a small area, such as within a building or a few buildings. A LAN is normally owned by a single organization.

Medium (or Multiple) Access Control (MAC): The process that determines which node has the right to transmit in a channel, or medium, at a given time. *Multiple access control* emphasizes enabling multiple users, or nodes, to access the channel.

Sensor Network: A network of embedded computers equipped with sensors and wireless communication devices. Most sensor nodes are powered by batteries and have limited computing resources.

Wireless LAN: A widely used LAN technology based on wireless communications; the current wireless LAN standard is the IEEE 802.11.

INTRODUCTION

Launched in May 1998, Bluetooth wireless technology rapidly has become one of the most well-known means of communication in the information technology industry. The unusual name *Bluetooth* itself has garnered much attention (I discuss the origins of this name later), but the main reason for the focus that the technology receives from so many companies and individuals is the capabilities that it brings to mobile computing and communication.

This chapter discusses many facets of Bluetooth wireless technology—its origins; the associated Bluetooth Special Interest Group; its applications, especially in personal area networks; how it works; and how it addresses security issues. I also present numerous references where more information can be found about this exciting way to form wireless personal area networks (WPANs) that allow mobile devices to communicate with one another.

BLUETOOTH WIRELESS TECHNOLOGY

Bluetooth wireless technology uses radio frequency (RF) to accomplish wireless communication. It operates in the 2.4 GHz frequency spectrum; the use of this frequency range allows Bluetooth devices to be used virtually worldwide without requiring a license for operation. Bluetooth communication is intended to operate over short

distances (up to approximately 100 m, although the nominal range used by most Bluetooth devices is about 10 m). Restricting communication to short ranges allows for low-power operation, so Bluetooth technology is particularly well suited for use with battery-powered personal devices that can be used to form a WPAN. Both voice and data can be carried over Bluetooth communication links, making the technology suitable for connecting both computing and communication devices, such as mobile phones, personal digital assistants (PDAs), pagers, and notebook computers. Table 1 summarizes these key attributes of Bluetooth wireless technology.

Bluetooth wireless technology originally was designed for cable replacement applications, intended to remove the need for a cable between any two devices to allow them to communicate. For example, a cable might be used to connect two computers to transfer files, to connect a PDA cradle to a computer to synchronize data, or to connect a headset to a telephone for hands-free voice calls. This sort of wired operation can often be cumbersome, because the cables used are frequently special-purpose wires intended to connect two specific devices; hence, they are likely to have special connectors that make them unsuitable for general-purpose use. This can lead to “cable clutter”—the need for many cables to interconnect various devices. Mobile users may find this especially burdensome because they need to carry their device cables with them to

Table 1: Key Bluetooth Technology Characteristics

Characteristic	Bluetooth Technology Attributes
Medium	Radio frequency in the 2.4 GHz globally unlicensed spectrum
Range	Nominally 10 m; optionally up to 100 m
Power	Low-power operation, suitable for battery-powered portable devices
Packet types	Voice and data
Types of applications	Cable replacement, wireless personal area networks
Example applications	Network access, wireless headsets, wireless data transfer, cordless telephony, retail and mobile e-commerce, travel and mobility, and many other applications

connect the devices when they are away from home, and, even with a large collection of cables, it is unlikely that all of the devices can be plugged together. Nonmobile environments, too, can suffer from cable clutter. In a home or office, wires used to connect, say, computer peripherals or stereo speakers limit the placement of these items, and the cables themselves become obstacles.

Bluetooth technology attempts to solve the problem of cable clutter by defining a standard communication mechanism that can allow many devices to communicate with one another without wires. The next section explores the genesis and evolution of Bluetooth wireless communication.

Origins

The genesis of Bluetooth wireless technology generally is credited to Ericsson, where engineers were searching for a method to enable wireless headsets for mobile telephones. Realizing that such a short-range RF technology could have wider applications, and further realizing that its likelihood for success would be greater as an industry standard rather than a proprietary technology, Ericsson approached other major telephone, mobile computer, and electronics companies about forming an industry group to specify and standardize a general-purpose, short-range, low-power form of wireless communication. This small group became the Bluetooth Special Interest Group (SIG), discussed later.

Of special interest to many is the name “Bluetooth.” Such a name for an industry initiative is unusual. A two-part newsletter article (Kardach 2001) offers a full explanation of the name’s origin; the salient points follow here. Some of the first technologists involved in early discussions about a short-range wireless technology were history buffs, and the discussion at some point turned to Scandinavian history. A key figure in Scandinavian history is tenth-century Danish king Harald Blåtand, who is credited with uniting parts of Scandinavia. It is said that a loose translation of his surname to English produces “blue tooth.” Those involved in early discussions of this technology recognized that it could unite the telecommunications and information technology (IT) industries, and hence they referred to it as “Bluetooth,” after King Harald. At that time, Bluetooth was considered a temporary code name for the project. When the time came to develop an official name for the technology and its associated special interest group, the name Bluetooth was chosen after considering several alternatives. Today, this is the trademarked name of the technology and the incorporated entity (the Bluetooth SIG, discussed next) that manages it. In fact, the SIG publishes rules and guidelines (Bluetooth SIG 2006a) for using the term.

The Bluetooth Special Interest Group

Formed in early 1998 and announced in May of that year, the Bluetooth SIG originally was a rather loosely knit group of five companies: Ericsson, Intel, IBM, Nokia, and Toshiba. These companies established themselves as Bluetooth SIG promoter members and formed the core of the SIG. Other companies were invited to join as adopter

members, and the SIG’s membership grew rapidly. The promoter companies, along with a few invited experts, developed the original versions of the Bluetooth specification (detailed later).

In December 1999, four additional companies—3Com, Lucent, Microsoft, and Motorola—were invited to join the group of promoter companies (later Lucent’s promoter membership was transferred to its spin-off company, Agere Systems). By this time, the SIG’s membership had grown to more than 2,000 companies. In addition to promoters and adopters, a third membership tier, called “associate member,” also was defined. Companies may apply to become associate members and must pay membership fees. Adopter membership is free and open to anyone. In general, promoter and associate members develop and maintain the Bluetooth specification; adopter members may review specification updates before their public availability.

The SIG’s original purpose was to develop the Bluetooth specification, but it has taken on additional responsibilities over time. In 2001, the SIG incorporated and instituted a more formal structure for the organization, including a board of directors that oversees all operations, a technical organization led by the Bluetooth Architecture Review Board (BARB), a marketing arm, and a legal group. The SIG continues to develop and maintain the specification and promote the technology, including sponsoring developers’ conferences and other events. One important function of the SIG is to manage the Bluetooth qualification program, in which products are tested for conformance to the specification. All Bluetooth products must undergo qualification testing. In 2006, the SIG is going strong, with eight promoter companies and more than 4,000 members. The Bluetooth Web site (Bluetooth SIG 2006b) offers more details about the SIG, its members, and its current organization.

Wireless Personal Area Networks

A personal area network (PAN) generally is considered to be a set of communicating devices that someone carries with him or her. A wireless PAN (WPAN), of course, is a set of devices that communicates without cables, such as through the use of Bluetooth technology. One can imagine a sphere of connectivity that surrounds a person and moves with her or him, so that all of the devices in the WPAN remain in communication with one another.

WPANs need only short-range communication capability to cover the personal area, in contrast with local area networks (LANs) or wide area networks (WANs), which need to communicate across greater distances using an established infrastructure. One source (Miller 2001) contrasts PANs, LANs, and WANs, and particularly Bluetooth technology as a WPAN solution versus Institute of Electrical and Electronics Engineers (IEEE 1999) 802.11 WLAN technology.

The usefulness of a WPAN derives primarily from the ability of individual devices to communicate with one another in an ad hoc manner. Each device still can specialize in certain capabilities but can “borrow” the capabilities of other devices to accomplish certain tasks. For example, a PDA is useful for quickly accessing personal

information, such as appointments and contacts. A mobile telephone can be used to contact people whose information is stored in the PDA. Hence, a user might look up the telephone number of an associate and then dial that number on the mobile phone. With a WPAN, however, this process can be automated: once the telephone number is accessed, the PDA software could include an option to dial the specified phone number automatically on the mobile telephone within the WPAN, using wireless communication links to transmit the dialing instructions to the phone. When combined with a wireless headset in the same WPAN, this could enable a more convenient device usage model for the user, who might never need to handle the mobile telephone at all (it could remain stored in a briefcase). Moreover, the user interface of the PDA is likely to be easier to use than a telephone keypad for retrieving contact information. This allows each of the devices (PDA, mobile phone, and wireless headset, in this example) to be optimized to perform the specific tasks that it does best. The capabilities of each device are accessed from other devices via the WPAN. Contrast this with an alternative usage model, the “all-in-one” device (such as a PDA that also functions as a mobile telephone). Such multifunction devices might tend to be cumbersome and are more difficult to optimize for specific functions.

Because it was developed primarily to replace cables that connect mobile devices, Bluetooth wireless communication is an ideal WPAN technology. Indeed, most of the popular usage scenarios for Bluetooth technology originate in a WPAN of some sort, connecting personal devices to one another or to other networks in proximity. The use of Bluetooth communication links in WPANs is illustrated next, in an examination of various Bluetooth applications.

Bluetooth Applications

Because Bluetooth technology primarily is about replacing cables, many of its applications involve well-known usage scenarios. The value that Bluetooth communication adds to these types of applications derives from the ability to accomplish them without wires, enhancing mobility and convenience. For example, dialup networking is a task commonly performed by many individuals, especially mobile professionals. One of the original usage scenarios used to illustrate the value of Bluetooth technology involves performing dialup networking wirelessly; with the use of a mobile computer and a mobile phone, both equipped with

Bluetooth communication, dialup networking no longer is constrained by cables. This application and others are detailed next.

Basic Cable Replacement Applications

These applications comprise the original set of usage models envisioned for Bluetooth wireless technology. When the SIG was formed and the technology began to be popularized, these applications were touted as the most common ways in which Bluetooth wireless communication would be used. Although many other, perhaps more sophisticated, applications for Bluetooth technology have been discovered and specified, these original usage models formed the basis of the “starter set” of Bluetooth applications, and they offer a good basis for understanding Bluetooth wireless communication. Nearly all of these early applications involve a mobile computer or a mobile telephone, and, for the most part, they involve performing typical existing tasks wirelessly.

One such application, already mentioned, is dialup networking. In this application, a Bluetooth communication link replaces the wire (typically a serial cable) between a computer and a telephone. When the telephone is also a mobile device, the network connection can be entirely wireless; a Bluetooth wireless link exists between the computer and the telephone, and a wide-area communications link (using typical cellular technology, such as the global system for mobile communication [GSM], time division/demand multiple access [TDMA], or others) carries the network traffic, using the mobile telephone as a wireless modem. Figure 1 depicts this usage model.

A variant of this application uses direct (rather than dialup) connection to a network such as the Internet. In this case, the Bluetooth link allows a computer to connect to a network such as a LAN without using a cable. Together, these two applications (wireless dialup networking and wireless LAN access) form one of the original usage models that the SIG called the *Internet bridge*. Both applications involve access to a network, using existing protocols, with the main benefit being the ability to access the network without the cables that typically are required to connect the network client computer.

Another type of cable replacement application involves data transfer from one device to another. One of the most common such usage models is transferring files from one computer to another. This can be accomplished with removable media (CDs, memory keys), with cables (via a

Figure 1: Dialup networking illustration

network or a direct connection), or wirelessly (using infrared or Bluetooth communication, to name two ways). Infrared file transfer is not uncommon, but it requires the two devices to have a line of sight between them. Bluetooth file transfer operates similarly to that of Infrared Data Association (IrDA) infrared file transfer (in fact, the Bluetooth protocol stack, discussed later, is designed such that the same application can be used over either transport medium). Bluetooth communication, being RF based, does not require a line of sight between the two devices, however. Moreover, through the use of standard data formats, such as *vCard* and *vCalendar* (Internet Mail Consortium 1996) and others, objects other than files can be exchanged between devices using Bluetooth links in a manner similar to that used with IrDA. So, for example, electronic business cards, calendar appointments, and contact information can be shared wirelessly among devices.

Building on this capability to exchange data objects is the application that allows these same objects to be synchronized. This means that data sets on two devices reflect the same information at the point in time when they are synchronized. Hence, in addition to simply sending a copy of contact information or a calendar appointment from one device to another, the full address book or calendar can be synchronized between the two devices so that they have the same set of contacts or appointments. This allows a user to enter information on any convenient device and then have that information reflected on other devices by synchronizing with those devices. In addition to the benefit of performing these tasks wirelessly, by using standard protocols and data formats, information can be exchanged easily among many kinds of devices. Specialized cables to connect two computers, or custom cradles to connect a PDA to a computer, are not needed once Bluetooth technology enters the picture. Instead, the same data can be exchanged and synchronized to and from notebook computers, PDAs, mobile phones, pagers, and other devices. This illustrates a hallmark of the value of Bluetooth technology: a single standard wireless link can replace many cables of various types, allowing devices that otherwise might not be able to be connected to communicate easily.

Another data transfer application is related to those just described, but it has a distinguished usage model because of the kind of data it transfers, namely, image data. The SIG called this original usage model the *instant postcard*, and it involves transferring pictures from one device to another. One reason that this application is separately described is because it involves the use of a digital camera. Today, when a camera captures new images, they typically are loaded onto a computer of some sort (or perhaps a television or similar video device) to be displayed. Through the use of Bluetooth wireless technology, this image transfer can be accomplished more easily, but, once again, this standard form of wireless link enables the same data to be transferred to other types of devices. For example, rather than uploading photos to a computer, the photos might be transferred to a mobile phone. Even if the phone's display is not suitable for viewing the photo, it still could be e-mailed to someone who could view it on his or her computer or other e-mail device.

Until now, this chapter has focused on applications involving data, but Bluetooth wireless technology is also designed to transport voice traffic (audio packets), and some of the cable replacement applications take advantage of this fact. The most notable of these is the wireless headset. Cabled headsets that connect to a mobile phone are widely used today to allow hands-free conversations. Bluetooth technology removes the cable from the headset to the telephone handset, enabling wireless operation that can allow the phone to be stowed away in a briefcase, pocket, or purse. In fact, as noted earlier, this particular application was the basis for the invention of Bluetooth technology. As with the previously discussed applications, however, once a standard wireless link is established, additional ways to connect other kinds of devices present themselves. For example, the same Bluetooth headset used with a mobile phone might also be used with a stationary telephone (again to allow hands-free operation and increased mobility) and a computer (to carry audio traffic to and from the computer). Furthermore, although Bluetooth wireless communication was not originally designed to carry more complex audio traffic (such as digital music), advances are being made that will allow it to do so. With this capability, the same wireless headset also could be used with home entertainment systems, car audio systems, and personal music players. Hence, the Bluetooth SIG dubbed this original usage model the *ultimate headset*.

A variation on the wireless headset usage model is the original usage model that the SIG called the *speaking laptop*. In this application, Bluetooth links carry audio data in the same manner as for the headset application, but in this case the audio data is routed between a telephone and a notebook computer's speaker and microphone, rather than to a headset. One usage scenario enabled with this application is that of using the notebook computer as a speakerphone: a call made to or from a mobile telephone can be transformed into a conference call ("put on the speaker") by using the speaker and microphone built into nearly all portable (and desktop) computers.

Cordless telephony is another application for Bluetooth technology. With a Bluetooth voice access point, or cordless telephone base station, a standard cellular mobile telephone also can be used as a cordless phone in a home or office. The Bluetooth link carries the voice traffic from the handset to the base station, with the call then being carried over the normal wired telephone network. This allows mobile calls to be made without incurring cellular usage charges. In addition, two handsets can function as "walkie-talkies" or an intercom system, using direct Bluetooth links between them, allowing two parties to carry on voice conversations in a home, office, or public space without any telephone network at all. Because a single mobile telephone can be used as a standard cellular phone, a cordless phone, and an intercom, the SIG called this original cordless telephony application the *three-in-one phone* usage model.

Additional Applications

Although Bluetooth wireless technology was developed especially for cable-replacement applications such as those just cited, many observers quickly realized that Bluetooth communication could be used in other ways,

too. Here I describe a few of the many other applications of Bluetooth technology. For the most recent information about additional Bluetooth applications, see the Bluetooth Web site (Bluetooth SIG 2006b).

The Bluetooth SIG focused primarily on the cable-replacement applications already discussed in the original specifications that it released. The SIG has developed numerous additional profiles (detailed later) for other types of Bluetooth applications. Among these are more robust personal area proximity networking, human interface devices, printing, local positioning, multimedia, and other applications.

Bluetooth personal area networking takes advantage of the ability of Bluetooth devices to establish communication with one another based on their proximity, so that ad hoc networks can be formed. The Bluetooth network encapsulation protocol (BNEP) allows Ethernet packets to be transported via Bluetooth links, thus enabling many classic networking applications to operate in Bluetooth piconets (piconets are discussed at length in the section entitled “Bluetooth Operation”). This capability extends the Bluetooth WPAN to encompass other devices. An example is the formation of an ad hoc Bluetooth network in a conference room with multiple meeting participants. Such a network could facilitate collaborative applications such as white-boarding, instant messaging, and group scheduling. Such applications could allow group editing of documents and scheduling of follow-up meetings, all in real time. Nonetheless, it should be noted that although this scenario resembles classic intranet- or Internet-style networking in some respects, Bluetooth personal area networking is not as robust a solution for true networking solutions as is a WLAN technology, such as IEEE 802.11.

Replacing desktop computer cables with Bluetooth communication links fundamentally is a cable-replacement application (originally dubbed the *cordless computer* by the SIG). The human interface device (HID) profile describes how Bluetooth technology can be used in wireless computer peripherals such as keyboards, mice, joysticks, and so on. The Bluetooth printing profiles specify methods for wireless printing using Bluetooth communication, including “walk up and print” scenarios that allow immediate printing from any device, including mobile telephones and PDAs, as well as notebook computers, to any usable printer in the vicinity. This application of Bluetooth technology can obviate the need for specialized network print servers and their associated configuration and administration tasks.

Another application that can be realized with Bluetooth wireless technology is local positioning. Bluetooth technology can be used to augment other technologies, such as global positioning systems (GPSs), especially inside buildings, where other technologies might not work well. Using two or more Bluetooth radios, local position information can be obtained in several ways. If one Bluetooth device is stationary (say, a kiosk), it could supply its position information to other devices within range. Any device that knows its own position can provide this information to other Bluetooth devices so that they can learn their current position. Sophisticated applications might even use signal strength information to derive more granular position information. Once position information is

known, it could be used with other applications, such as maps of the area, directions to target locations, or perhaps even locating lost devices. The Bluetooth local positioning working group is one of the Bluetooth working groups that develops specifications, including standard data formats and interchange methods, for applications such as local positioning.

Multimedia applications have become standard on most desktop and notebook computers, and the Bluetooth SIG has defined profiles for transporting multimedia data, such as audio and video, in Bluetooth environments.

Another emerging application area is that of automotive Bluetooth applications. Using Bluetooth communication, wireless networks can be formed in cars. Devices from the WPAN can join the automobile’s built-in Bluetooth network to accomplish scenarios such as the following:

- Obtaining e-mail and other messages, using a mobile phone as a WAN access device, and transferring those messages to the car’s Bluetooth network, where they might be read over the car’s audio system using text-to-speech technology (and perhaps even composing responses using voice recognition technology)
- Obtaining vehicle information remotely, perhaps for informational purposes (for example, querying the car’s current mileage from the office or home) or for diagnostic purposes (for example, a wireless engine diagnostic system for automobile mechanics that does not require probes and cables to be connected to the engine)
- Sending alerts and reminders from the car to a WPAN when service or maintenance is required (for example, e-mail reminders that an oil change is due or in-vehicle or remote alerts when tire pressure is low or other problems are diagnosed by the vehicle’s diagnostic systems)

Several models of cars offer Bluetooth wireless technology today. This area is likely to prove to be an exciting and rapidly growing domain for the use of Bluetooth wireless technology.

These applications are only some of the potential uses for Bluetooth wireless technology. The SIG currently specifies more than thirty different profiles that describe different ways to use Bluetooth technology, and many other domains are being explored or will be invented in the future. Other noteworthy applications for Bluetooth wireless communications include mobile e-commerce, medical, and travel technologies. Bluetooth devices such as mobile phones or PDAs might be used to purchase items in stores or from vending machines; wireless biometrics and even Bluetooth drug dispensers might appear in the future (the 2.4 GHz band in which Bluetooth operates is called the industrial, scientific, and medical band); and travelers could experience enhanced convenience by using Bluetooth devices for anytime, anywhere personal data access and airline and hotel automated check-in.

The Bluetooth Protocol Stack

A complete discussion of the Bluetooth protocol stack is outside the scope of this chapter. Numerous books, including Miller and Bisdikian (2000) and Bray and Sturman (2000), offer more in-depth discussions of Bluetooth

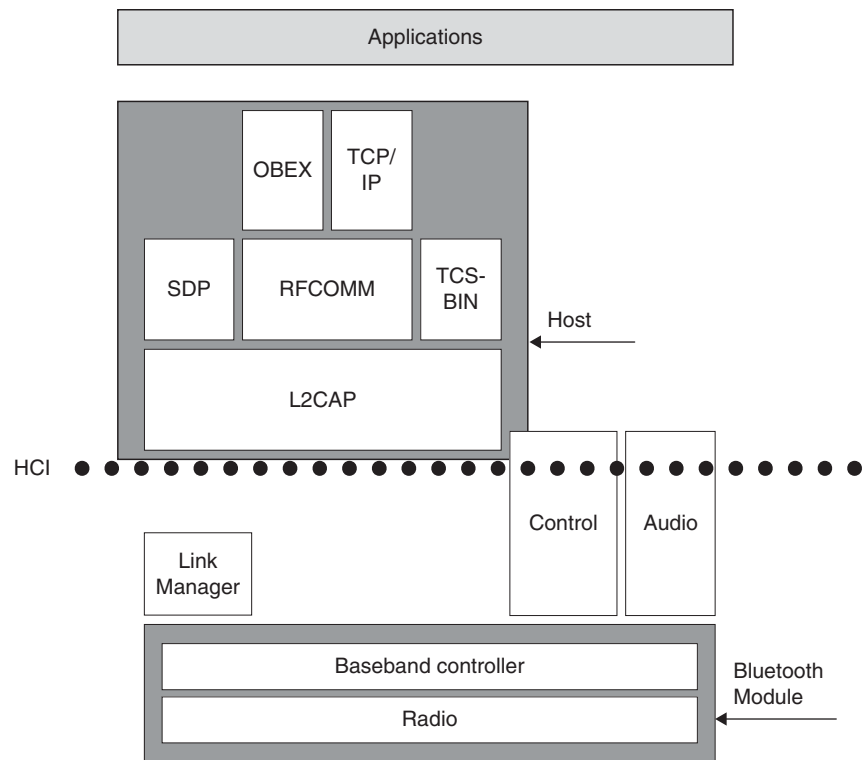

Figure 2: Bluetooth protocol stack

protocols. Here, we present an overview of Bluetooth operation and how the various protocols may be used to accomplish the applications already discussed. A typical Bluetooth stack is illustrated in Figure 2. Each layer of the stack is detailed next.

Radio, Baseband, and Link Manager

These three protocol layers constitute the Bluetooth module. Typically, this module is an electronics package containing hardware and firmware. Today, many manufacturers supply Bluetooth modules.

The radio consists of the signal-processing electronics for a transmitter and receiver (transceiver) to allow RF communication via an air interface between two Bluetooth devices. As noted earlier, the radio operates in the 2.4 GHz spectrum, specifically in the frequency range of 2.400 to 2.4835 GHz. This frequency range is divided into seventy-nine channels (along with upper and lower guard bands), with each channel having a 1 MHz separation from its neighbors. *Frequency hopping* is employed in Bluetooth wireless communication; each packet is transmitted on a different channel, with the channels being selected pseudo-randomly, based on the clock of the master device (master and slave devices are described in more detail later). The receiving device knows the frequency-hopping pattern and follows the pattern of the transmitting device, hopping to the next channel in the pattern to receive the transmitted packets.

The Bluetooth specification defines three classes of radios, based on their maximum power output:

- 1 mW (0dBm)
- 2.5 mW (4dBm)
- 100 mW (20dBm)

Increased transmission power offers a corresponding increase in radio range; the nominal range for the 0 dBm radio is 10 m, whereas the nominal range for the 20 dBm radio is 100 m. Of course, increased transmission power also requires a corresponding increase in the energy necessary to power the system, so higher-power radios will draw more battery power. The basic cable replacement applications (indeed, most Bluetooth usage scenarios described here) envision the 0 dBm radio, which is considered the standard Bluetooth radio and is the most prevalent in devices. The 0 dBm radio is sufficient for most applications, and its low power consumption makes it suitable for use on small, portable devices.

Transmitter and receiver characteristics such as interference, tolerance, sensitivity, modulation, and spurious emissions are outside the scope of this chapter but are detailed in the Bluetooth specification (Bluetooth SIG 2004).

The baseband controller controls the radio and typically is implemented as firmware in the Bluetooth module. The controller is responsible for all of the various timing and raw data-handling aspects associated with RF communication, including the frequency hopping just mentioned, management of the time slots used for transmitting and receiving packets, generating air-interface packets (and causing the radio to transmit them), and parsing air-interface packets (when they are received by the radio). Packet generation and reception involves many considerations, including the following:

- Generating and receiving packet payload
- Generating and receiving packet headers and trailers
- Dealing with the several packet formats defined for Bluetooth communication

- Error detection and correction
- Address generation and detection
- Data whitening (a process by which the actual data bits are rearranged so that the occurrence of zero and one bits in a data stream is randomized, helping to overcome DC bias)
- Data encryption and decryption

Not all of these operations are necessarily performed on every packet; there are various options available for whether a particular transformation is applied to the data, and, in some cases (such as error detection and correction), there are several alternatives that may be employed by the baseband firmware.

The link manager, as its name implies, manages the link layer between two Bluetooth devices. Link managers in two devices communicate using the link manager protocol (LMP). LMP consists of a set of commands and responses to set up and manage a baseband link between two devices. A link manager on one device communicates with a link manager on another device. (Indeed, this is generally the case for all of the Bluetooth protocols described here; a particular protocol layer communicates with its corresponding layer in the other device, using its own defined protocol. Each protocol is passed to the next successively lower layer, where it is transformed to that layer's protocol, until it reaches the baseband, where the baseband packets that encapsulate the higher-layer packets are transmitted and received via the air interface.) LMP setup commands include those for authenticating the link with the other device; setting up encryption, if desired, between the two devices; retrieving information about the device at the other end of the link, such as its name and timing parameters; and swapping the master and slave roles (detailed later) of the two devices. LMP management commands include those for controlling the transmission power; setting special power-saving modes, called hold, park, and sniff; and managing quality-of-service (QoS) parameters for the link. Because LMP messages deal with fundamental characteristics of the communication link between devices, they are handled in an expedited manner, at a higher priority than the normal data that are transmitted and received.

Control and Audio

The control and audio blocks in Figure 2 are not actual protocols. Instead, they represent means by which the upper layers of the stack can access lower layers. The control functions can be characterized as methods for inter-protocol-layer communication. These could include requests and notifications from applications, end users, or protocol layers that require action by another protocol layer, such as setting desired QoS parameters, requests to enter or terminate power-saving modes, or requests to search for other Bluetooth devices or change the discoverability of the local device. Often, these take the form of a user-initiated action, via an application, that requires the link manager (and perhaps other layers) to take some action.

The audio block in Figure 2 represents the typical path for audio (voice) traffic. Recall that Bluetooth wireless technology supports both data and voice. Data packets

traverse through the L2CAP layer (described later), but voice packets typically are routed directly to the baseband, because audio traffic is isochronous and hence time critical. Audio traffic usually is associated with telephony applications, for which data traffic is used to set up and control the call, and voice traffic serves as the content of the call. Audio data can be carried over Bluetooth links in two formats:

- Pulse code modulation (PCM), with either a-law or μ -law logarithmic compression
- Continuous variable slope delta (CVSD) modulation, which works well for audio data with relatively smooth continuity, usually the case for typical voice conversations

Host-Controller Interface

The host-controller interface (HCI) is an optional interface between the two major components of the Bluetooth stack: the *host* and the *controller*. As shown in Figure 2 and described earlier, the radio, baseband controller, and link manager constitute the module, which is often, but not necessarily, implemented in a single electronics package. Such a module can be integrated easily into many devices, with the remaining layers of the stack residing on the main processor of the device (such as a notebook computer, mobile phone, or PDA). These remaining layers, which are described next, are referred to as the host portion of the stack.

Figure 2 illustrates a typical “two-chip” solution in which the first “chip” is the Bluetooth module and the second “chip” is the processor in the device on which the host software executes. (The module itself might have multiple chips or electronic subsystems for the radio, the firmware processor, and other external logic.) In such a system, the HCI allows different Bluetooth modules to be interchanged in a device, because it defines a standard method for the host software to communicate with the controller firmware that resides on the module. So, at least in theory, one vendor's Bluetooth module could be substituted for another, so long as both faithfully implement the HCI. Although this is not the only type of partitioning that can be used when implementing a Bluetooth system, the SIG felt it was common enough that a standard interface should be defined between the two major components of the system. A Bluetooth system could be implemented in an “all-in-one” single module, where the host and controller reside together in the same physical package (often called a “single-chip” solution), although, in this case, the HCI might still be used as an internal interface. When the two-chip solution is used, the physical layer for the HCI (that is, the physical connection between the host and the controller) could be one of several types. The Bluetooth specification defines three particular physical layers for the HCI:

- Universal serial bus (USB)
- Universal asynchronous receiver/transmitter (UART)
- RS-232 serial port

Other HCI transports could be implemented; the Bluetooth specification currently contains details and considerations for these three.

Logical Link Control and Adaptation Protocol

The logical link control and adaptation protocol (L2CAP) layer serves as a “funnel” through which all data traffic flows. As discussed earlier, voice packets typically are routed directly to the baseband, whereas data packets flow to and from higher layers, such as applications, to the baseband via the L2CAP layer.

The L2CAP layer offers an abstraction of lower layers to higher-layer protocols. This allows the higher layers to operate using more natural data packet formats and protocols, without being concerned about how their data are transferred over the air interface. For example, the service discovery protocol (SDP) layer (discussed next) defines its own data formats and protocol data units. At the SDP layer, only the service discovery protocol needs to be handled; the fact that SDP data must be separated into baseband packets for transmission and aggregated from baseband packets for reception is not a concern at the SDP layer, nor are any of the other operations that occur at the baseband (such as encryption, whitening, and so on). This is accomplished because the L2CAP layer performs operations on data packets. Among these operations are segmentation and reassembly, whereby the L2CAP layer breaks higher-layer protocol data units into L2CAP packets, which in turn can be transformed into baseband packets; the L2CAP layer conversely can reassemble baseband packets into L2CAP packets that in turn can be transformed into the natural format of higher layers of the stack.

An L2CAP layer in one Bluetooth stack communicates with another, corresponding L2CAP layer in another Bluetooth stack. Each L2CAP layer can have many channels. L2CAP channels identify data streams between the L2CAP layers in two Bluetooth devices. (L2CAP channels should not be confused with baseband channels used for frequency hopping; L2CAP channels are logical identifiers between two L2CAP layers.) An L2CAP channel often is associated with a particular upper layer of the stack, handling data traffic for that layer, although there need not be a one-to-one correspondence between channels and upper-layer protocols. An L2CAP layer might use the same protocol on multiple L2CAP channels. This illustrates another data operation of the L2CAP layer: protocol multiplexing. Through the use of multiple channels and a protocol identifier (called a protocol-specific multiplexer, or PSM), L2CAP allows various protocols to be multiplexed (flow simultaneously) over the air interface. The L2CAP layer sorts out which packets are destined for which upper layers of the stack.

Service Discovery Protocol

The SDP layer provides a means by which Bluetooth devices can learn, in an ad hoc manner, which services are offered by each device. Once a connection has been established, devices use the SDP to exchange information about services. An SDP client queries an SDP server to inquire about services that are available; the SDP server responds with information about services that it offers. Any Bluetooth device can be either an SDP client or an SDP server, acting in one role or the other at different times.

SDP allows a device to inquire about specific services in which it is interested (called *service searching*) or to

perform a general inquiry about any services that happen to be available (called *service browsing*). A device can perform an SDP service search to look for, say, printing services in the vicinity. Any devices that offer a printing service that matches the query can respond with a “handle” for the service; the client then uses that handle to perform additional queries to obtain more details about the service. Once a service is discovered using SDP, other protocols are used to access and invoke the service; one of the items that can be discovered using SDP is the set of protocols that is necessary to access and invoke the service.

SDP is designed to be a lightweight discovery protocol that is optimized for the dynamic nature of Bluetooth piconets. SDP can coexist with other discovery and control protocols; for example, the Bluetooth SIG has published a specification for using the Universal Plug and Play (UPnP) discovery and control technology over Bluetooth links.

RFCOMM

As its name suggests, the RFCOMM layer defines a standard serial communications protocol, specifically one that emulates serial port communication (the “RF” designates radio frequency wireless communication; the “COMM” portion suggests a serial port, commonly called a COM port in the personal computer realm). RFCOMM emulates a serial cable connection and provides the abstraction of a serial port to higher layers in the stack. This is particularly valuable for Bluetooth cable-replacement applications, because so many cable connections—modems, infrared ports, camera and mobile phone ports, printers, and others—use some form of a serial port to communicate.

RFCOMM is based on the European Telecommunications Standards Institute (ETSI) TS07.10 protocol (ETSI 1999), which defines a multiplexed serial communications channel. The Bluetooth specification adopts much of the TS07.10 protocol and adds some Bluetooth adaptation features. The presence of RFCOMM in the Bluetooth protocol stack is intended to facilitate the migration of existing wired serial communication applications to wireless Bluetooth links. By presenting higher layers of the stack with a virtual serial port, many existing applications that already use a serial port can be used in Bluetooth environments without any changes. Indeed, many of the cable-replacement applications cited earlier, including dialup networking, LAN access, headset, and file and object exchange, use RFCOMM to communicate. Because RFCOMM is a multiplexed serial channel, many serial data streams can flow over it simultaneously; each separate serial data stream is identified with a server channel, in a manner somewhat analogous to the channels used with L2CAP.

Telephony Control Specification-Binary

The telephony control specification-binary (TCS-BIN) is a protocol used for advanced telephony operations. Many of the Bluetooth usage scenarios involve a mobile telephone, and some of these use the TCS-BIN protocol. TCS-BIN is adopted from the ITU-T Q.931 standard (International Telecommunications Union 1998), and it includes functions for call control and managing wireless

user groups. Typically, TCS-BIN is used to set up and manage voice calls; the voice traffic that is the content of the call is carried as audio packets, as described earlier. Applications such as the three-in-one phone usage model use TCS-BIN to enable functions such as using a mobile phone as a cordless phone or an intercom. In these cases, TCS-BIN is used to recognize the mobile phone so that it can be added to a wireless user group that consists of all the cordless telephone handsets used with a cordless telephone base station. TCS-BIN is also used to set up and control calls between the handset and the base station (cordless telephony) or between two handsets (intercom).

TCS-BIN offers several advanced telephony functions; devices that support TCS-BIN can obtain knowledge of and directly communicate with any other devices in the TCS-BIN wireless user group, essentially overcoming the master-slave relationship of the underlying Bluetooth piconet (detailed later). It should be noted that not all Bluetooth telephony applications require TCS-BIN; an alternative method for call control is the use of a modem control protocol, commonly called AT commands, via the RFCOMM serial interface. This latter method is used for the headset, dialup networking, and fax profiles.

Adopted Protocols

Although several layers of the Bluetooth protocol stack were developed specifically to support Bluetooth wireless communication, other layers are adopted from existing industry standards. I already have noted that RFCOMM and TCS-BIN are based on existing specifications. In addition to these, protocols for file and object exchange and synchronization are adopted from the IrDA, and Internet networking protocols are used in some applications.

The IrDA's object exchange (OBEX) protocol is used for the file and object transfer, object push, and synchronization usage models. OBEX originally was developed for infrared wireless communication, and it maps well to Bluetooth wireless communication. OBEX is a relatively lightweight protocol for data exchange, and several well-defined data types—including electronic business cards, e-mail, short messages, and calendar items—can be carried within the protocol. Hence, the Bluetooth SIG adopted OBEX for use in its data exchange scenarios; by doing so, existing infrared applications can be used via Bluetooth links, often with no application changes. In addition, the infrared mobile communications (IrMC) protocol is used for the synchronization usage model. Typically, infrared communication occurs via a serial port, so the adopted IrDA protocols operate via RFCOMM in the Bluetooth protocol stack.

Networking applications such as dialup networking and LAN access use standard Internet protocols, including point-to-point protocol (PPP), Internet protocol (IP), user datagram protocol (UDP), and transmission control protocol (TCP). As shown in Figure 2, these protocols operate via the RFCOMM protocol. Once a Bluetooth RFCOMM connection is established between two devices, PPP can be used as a basis for UDP-IP and TCP-IP networking packets. This enables typical networking applications, such as network dialers, e-mail programs, and browsers, to operate via Bluetooth links, often with no changes to the applications.

Bluetooth Profiles

I have presented an overview of the Bluetooth protocols, which are described in the Bluetooth core specification (Bluetooth SIG 2004). The Bluetooth SIG publishes multiple volumes of the specification, some of which define the Bluetooth profiles. Profiles offer additional guidance to developers beyond the specification of the protocols. Essentially, a profile is a formalized usage case that describes how to use the protocols (including which protocols to use, which options are available, and so on) for a particular application. Profiles were developed to foster interoperability; they provide a standard basis for all implementations to increase the likelihood that implementations from different vendors will work together, so that end users can have confidence that Bluetooth devices will interoperate with one another. In addition to the profile specifications, the SIG offers other mechanisms intended to promote interoperability; among these are the Bluetooth Qualification Program (a definition of testing that a Bluetooth device must undergo) and unplugfests (informal sessions during which many vendors can test their products with one another). Detailed discussions of these programs are outside the scope of this chapter; but more information about the profiles and other SIG programs is available on the Bluetooth Web site (Bluetooth SIG 2006b).

Our earlier discussion of Bluetooth applications presented several usage models for Bluetooth wireless communication. Many of these applications have associated profiles. For example, the dialup networking profile defines implementation considerations for the dialup networking application. Most of the applications cited here have associated profiles, and many profiles have been developed and new ones are being developed and published by the SIG; the official Bluetooth Web site (Bluetooth SIG 2006b) has a current list of available specifications. In addition, there are some fundamental profiles that describe basic Bluetooth operations that are necessary for most applications. Profiles such as the generic access profile, service discovery profile, RFCOMM profile, and others provide these core operations that enable many of the more advanced usage scenarios.

Profiles define mechanisms for file and object transfer, object push, synchronization, dialup networking, fax, headset, LAN access, cordless telephony, and intercom. The telephony (TCS-BIN) profile includes elements that are common to cordless telephony and intercom applications; similarly, the generic object exchange profile describes the common elements used for particular object exchange applications such as object transfer and synchronization, and the serial port profile defines operations used by all applications that use the RFCOMM serial cable-replacement protocol. Note that the generic object exchange profile derives from the serial port profile; this is because OBEX operates via RFCOMM in the Bluetooth protocol stack.

Other profiles describe fundamental operations for Bluetooth communication. The service discovery application profile describes how a service discovery application uses the service discovery protocol (described earlier). The generic access profile is common to all applications; it defines the basic operations that Bluetooth devices use to establish connections, including how devices become discoverable and connectable, security considerations for

connections, and so on. The generic access profile also includes a common set of terminology used in other profiles; this is intended to reduce ambiguity in the specification. The generic access and service discovery application profiles are mandatory for all Bluetooth devices to implement, because they form the basis for interoperable devices.

Numerous other profiles build on the fundamental profiles to describe other applications, including basic imaging, audio and video control and transport, printing, and personal area networking. The Bluetooth Web site (Bluetooth SIG 2006b) lists all of the current profiles. Other works, including Miller and Bisdikian (2000), delve more deeply into the Bluetooth profiles.

Bluetooth Operation

Having discussed WPANs, Bluetooth applications, protocols, and profiles, I now turn our attention to some of the fundamental concepts of Bluetooth operation, illustrating an example flow for a Bluetooth connection.

At the baseband layer, Bluetooth operates on a master-slave model. In general, the *master* device is the one that initiates communication with one or more other devices. *Slaves* are the devices that respond to the master's queries. In general, any Bluetooth device can operate as either a master or a slave at any given time. The master and slave roles are meaningful only at the baseband layer; upper layers are not concerned with these roles. The master device establishes the frequency-hopping pattern for communication with its slaves, using its internal clock values to generate the frequency-hopping pattern. Slaves follow the frequency-hopping pattern of the master(s) with which they communicate.

When a master establishes a connection with one or more slaves, a *piconet* is formed. To establish the connection, a master uses processes called *inquiry* and *paging*. A master can perform an inquiry operation, which transmits a well-defined data sequence across the full spectrum of frequency-hopping channels. An inquiry effectively asks, "Are there any devices listening?" Devices that are in *inquiry scan* mode (a mode in which the device periodically listens to all of the channels for inquiries) can respond to the master's inquiry with enough information for the master device to address the responding device directly. The inquiring (master) device may then choose to page the responding (slave) device. The page is also transmitted across the full spectrum of frequency-hopping channels; the device that originally responded to the inquiry can enter a *page scan* state (a state in which it periodically listens to all of the channels for pages), and it can respond to the page with additional information that can be used to establish a baseband connection between the master and the slave. The master can repeat this process and establish connections with as many as seven slaves at a time. Hence, a piconet consists of one master and up to seven active slaves; additional slaves can be part of the piconet, but only seven slaves can be active at one time. Slaves can be "parked" (made inactive) so that other slaves can be activated. Figure 3 illustrates a typical Bluetooth piconet. Note that a device could be a slave in more than one piconet at a time, or it could be a master

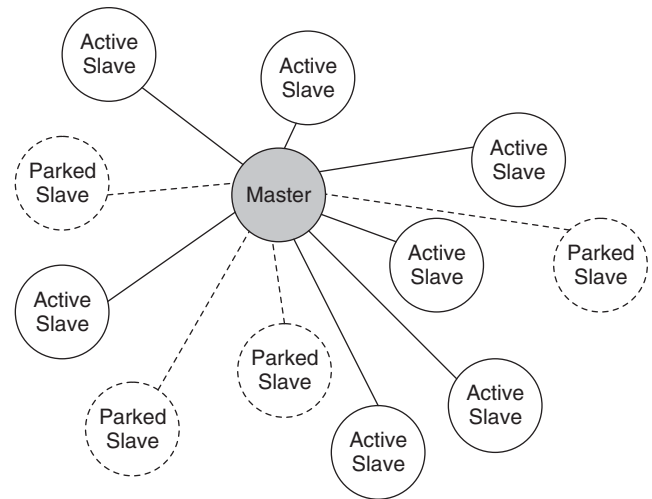

Figure 3: Example of a Bluetooth piconet

of one piconet and a slave in a second piconet. In these cases, the device participating in multiple piconets must use the appropriate frequency-hopping pattern in each piconet, so it effectively must split its time among all the piconets in which it participates. The Bluetooth specification calls such interconnected piconets *scatternets*.

Once a piconet is formed (a baseband connection exists between a master and one or more slave devices), higher-layer connections can be formed, and link manager commands and responses may be used to manage the link. At some point, it is likely that an L2CAP connection will be formed for data packets (even if the main content for a link is voice traffic, an L2CAP data connection will be needed to set up and manage the voice links). A Bluetooth device can have one data (L2CAP) connection and up to three voice connections with any other Bluetooth device at a given time (recall, however, that L2CAP connections can be multiplexed, so many different data streams can flow over the single L2CAP connection). Once an L2CAP connection is established, additional higher-layer connections can be established. If the devices are not familiar to one another already, it is likely that an SDP connection will be used to perform service discovery. RFCOMM and TCS-BIN connections also might be made, depending on the application. From here, applications can manage voice and data packets to accomplish their usage scenarios, which might be those defined by Bluetooth profiles or other ways to use Bluetooth wireless communication to accomplish a given task. Additional details about fundamental Bluetooth operations and connection establishment, including the various types of packets, master-slave communication protocols, and timing considerations, are outside the scope of this chapter but are detailed in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

Bluetooth Security

A noteworthy aspect of Bluetooth operation is security. In the wireless world, security justifiably is a key concern for device manufacturers, device deployers, and end users.

The Bluetooth specification includes security measures such as authentication and encryption, and the Bluetooth profiles discuss which security measures should be employed in various circumstances.

At the time that a link is established, Bluetooth devices may be required to authenticate themselves to each other. This is done using a shared-secret method (other methods such as those using public keys typically require some sort of central registry, which is not appropriate for WPANs that use ad hoc networking). The first device sends a randomly generated number to the second device, which performs some computation using a link key value and returns the result to the first device. If that value is the one expected by the first device, then it considers the second device authenticated. The second device might then, in turn, authenticate the first device so that the two devices are mutually authenticated with each other. Link keys are maintained by each device; a process called *pairing* can be used to generate a link key from an initialization key the very first time two devices are introduced to each other.

Once a link has been established, the data traffic over that link may be encrypted. The encryption key is derived from the link key, so devices that exchange encrypted traffic must have been already authenticated with each other. Bluetooth links support up to 128-bit encryption; the devices mutually agree on the encryption key size.

The Bluetooth profiles provide guidance about how and when to use authentication and encryption in Bluetooth wireless communication. The generic access profile described earlier defines three different security modes (nonsecure, service-level enforced security, and link-level enforced security) and the procedures to follow to achieve those levels of security in Bluetooth communications. Other profiles specify the security measures that should be used for various applications or scenarios. For example, the file-transfer profile requires that both authentication and encryption be supported, and it recommends that they be used; the dialup networking profile requires that all data be encrypted, in addition to device authentication.

Applications are free to impose additional security restrictions beyond those that are provided in the specification. For example, applications might choose to expose data or services only to authorized users or to implement more robust user authentication schemes. Certain applications might include other security mechanisms beyond those built into the Bluetooth devices, such as the use of public key infrastructure, certificates, or other methods. More details about the operation of Bluetooth security features are included in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

CONCLUSION

This introduction to Bluetooth wireless technology has touched on what can be done with the technology (Bluetooth applications), how it began, how it is managed (the Bluetooth SIG), and how it works (Bluetooth protocols, profiles, and operation, including security). The chapter focused on the application of Bluetooth wireless communication as a WPAN technology for connecting personal

portable devices. I have also presented several references in which this topic is explored in greater detail.

With tremendous industry backing, a design to work with both voice and data, the ability to replace cumbersome cables, and many new products being deployed on a regular basis, Bluetooth wireless technology is poised to become an important way for people to communicate for the foreseeable future. From its genesis as a method to provide a wireless headset for mobile phones, this technology named for a Danish king continues to spread across the planet.

GLOSSARY

Bluetooth Special Interest Group (SIG): An industry consortium that develops, promotes, and manages Bluetooth wireless technology, including the Bluetooth qualification program and the Bluetooth brand.

Bluetooth wireless technology: Name given to a wireless communications technology used for short-range voice and data communication, especially for cable-replacement applications.

Frequency-hopping spread spectrum A method of dividing packetized information across multiple channels of a frequency spectrum that is used in Bluetooth wireless communication.

IEEE 802.11: A wireless local area network standard developed by the Institute of Electrical and Electronics Engineers that is considered complementary to Bluetooth wireless technology.

IEEE 802.15.1: A wireless personal area network standard developed by the Institute of Electrical and Electronics Engineers that is based on Bluetooth wireless technology.

Infrared Data Association (IrDA): An industry consortium that specifies the IrDA infrared communication protocols, some of which are used in the Bluetooth protocol stack.

Piconet: A Bluetooth wireless technology term for a set of interconnected devices with one master and up to seven active slave devices.

Profile: In Bluetooth wireless technology, a specification for standard methods to use when implementing a particular application, with a goal of fostering interoperability among applications and devices.

Radio frequency (RF): Used in the Bluetooth specification to describe the use of radio waves for physical layer communication.

Wireless personal area network (WPAN): A small set of interconnected devices used by one person.

INTRODUCTION

Manmade satellites, working in orbit at significant altitude from the Earth, provide the possibility of guaranteeing visibility between points not in line of sight on the Earth due to limitations imposed by the Earth's spherical nature. Satellites actually represent an excellent, sometimes unique, means of complementing terrestrial facilities in order to complete the global information infrastructure (GII), of which every component (terrestrial cabled, terrestrial wireless, and satellite) must play the most suitable role to provide telecommunication connectivity (and hence services) anywhere and to anyone.

In this scenario, as long as the telecommunication systems assume an ever more important role in daily life (both personal and professional), satellites can represent a real added value to ensure global communications.

To introduce the basic concepts of satellite communications, a short history is presented. The rationale for using satellites is highlighted. The main characteristics of satellite systems are described, taking as a reference structure the Internet protocol stack. In addition, three standards will be presented; standardization and regulation activities will be introduced; and interoperability with terrestrial systems will be briefly addressed. Finally, conclusions are presented.

A SHORT HISTORY OF SATELLITE COMMUNICATIONS

The satellite age can be assumed to have begun in 1687 when Newton theorized his law of gravitational force. The paper "Extraterrestrial Relay" by Arthur Clarke (Clark 1945) published by *Wireless World* in October 1945, represents the first real milestone in satellite telecommunications. In that paper, Clarke designed the orbital configuration of a satellite constellation, using an orbit located at 35,800 km over the Earth's surface at the equator, coplanar with the equatorial plane, where the equilibrium between the gravitational force and the centrifugal force let a satellite appear fixed with respect to a point on

the Earth's surface. The geostationary constellation was composed of three manned satellites spaced 120° apart at equal angles to get global coverage and represents the reference configuration for most of the satellite systems. A later paper by John Pierce in 1954 titled "Telecommunication Satellites" suggests the use of unmanned satellites either in geostationary (GEO) or low Earth orbit (LEO).

In 1957 the Sputnik satellite launched by the former U.S.S.R. represented the first space mission. Even though it was not designed for telecommunication, the Sputnik mission validated the mechanical possibility of putting and keeping a body in orbit around the Earth.

After that, formal acts that actually set in motion the telecommunication satellite age include the Policy Statement on Communications Satellites signed by U.S. President John F. Kennedy in 1961; the U.S. Communications Satellite Act issued in 1962 with the birth of Comsat; the intergovernmental agreement Interim Arrangements for a Global Commercial Communications Satellite System, issued in 1964 with the birth of ICSC (Interim Communications Satellite Committee); and the formation of Intelsat (International Telecommunication Satellite, with headquarters in Washington D.C.), an intergovernmental organization.

Some experimental missions using LEO, MEO (medium Earth orbit), HEO (highly elliptical orbit), or GEO constellations (*Score* in December 1958, *Courier* in October 1960, *ECHO I* in August 1960, *TELSTAR I* in July 1962, *RELAY I* in December 1962, *TELSTAR II* in May 1963, *SYNCOM II* in July 1963, *ECHO II* in January 1964, *RELAY II* in January 1964, *SYNCOM III* in August 1964, and *MOLNIYA I* in April 1965) preceded the first commercial satellite (*Early Bird*) launched in April 1965 by Intelsat to provide intercontinental fixed services utilizing a constellation in geostationary orbit. In 1976, Marisat was the first system composed of three satellites in GEO orbit to provide mobile services. It preceded the foundation of INMARSAT (International Maritime Satellite, with headquarters in London), another intergovernmental organization that aimed to provide mobile satellite services and which, in 1982, launched the first

fully operational system targeted to maritime users. In the following years, INMARSAT provided service even on land masses and for aeronautical users.

In 1988, Omnitrac, the first system for land mobile services, was launched. In 1991, the Italian Italsat satellite represented the first satellite to work in the Ka band using a regenerative payload and multibeam antennas. In 1993, ACTS (Advanced Communication Technology Satellite), funded by the U.S. Congress, was launched as an experimental mission to further validate Ka-band technology, on-board processing, multibeam antennas, hopping beams, and on-board switching. In 1998, Iridium was the first satellite system designed for personal communications; it was followed a few years later by Globalstar. Both systems utilize LEO constellations. Despite limited commercial penetration, the two systems demonstrated the technical feasibility of implementing a network in space and they are currently operational.

SATELLITE SYSTEM CHARACTERISTICS

The use of satellites is justified for the following reasons:

- *Costs independent of distance (within one satellite coverage),*
- *Efficient and cost effective for collecting, broadcasting, and multicasting,*
- *Unique in areas with scarce or no infrastructures,*
- *Unique in case of disaster,*
- *Suitable for large coverage areas and long-range mobility,*
- *Relatively short deployment time,*
- *Flexible architecture,*
- *Bypass very crowded terrestrial networks,*
- *With the same terrestrial infrastructure, both fixed and mobile services,*
- *Extremely suitable for localization services worldwide.*

Assuming the Internet protocol stack as a reference, a brief description of the main characteristics of a satellite system for each layer will be presented.

Architecture

Orbits

The orbits can be classified according to eccentricity (circular or elliptical, where the Earth is located in one of the two focuses) or according to inclination with respect to the equatorial plane (equatorial, polar, or inclined) (Maral and Bousquet 2003; Lutz, Werner and Jahn 2003). Furthermore, they can be classified according to altitude: LEO, between 500 and 1,700 km; MEO, between 5,000 km and 10,000 km and at more than 20,000 km; GEO, at 35,800 km. The elliptical orbits can have the apogee between 39,000 km and 54,000 km. The altitudes below 500 km are not used to avoid atmospheric drag, whereas altitudes between LEO and MEO are not used to avoid the Van Allen belts.

The geostationary orbit theoretically allows a satellite to be in a fixed position with respect to the Earth's surface. Actually, the presence of many forces in addition to the

gravitational ones induces a precession movement that may require a tracking system for the ground terminals.

Satellite systems positioned in the GEO orbit are characterized by high delay (120–135 ms one-way) and high free space losses. The elevation angle α_m decreases as the latitude increases. On the other hand, the Earth can be covered with the simplest architecture, composed of just three satellites, but excluding polar regions (above 70° latitude N and below –70° latitude S). To match user distribution requirements, the position of the satellites on the arc may not be spaced 120° apart and in some orbital positions more than one satellite can be installed. If the aim is global coverage, two coverage strategies are applicable: (a) the satellites positioned over the three ocean regions (Atlantic, Pacific, and Indian), which is the largely preferred configuration although it maximizes propagation delay and free space losses (FSL) but can implement full connectivity through double hop, or (b) the satellites positioned over land masses (Europe/Africa, Asia/Australia, and America), which minimizes delay and FSL but must be interconnected through inter-satellite link (ISL) to achieve full connectivity.

LEO orbits allow better performance than GEO in terms of free space losses and propagation delay (20–40 ms), but a larger number of satellites is necessary to provide full coverage and real time interactive services (Maral and Bousquet 2003). Doppler effects and frequent handovers between spots and between satellites represent the main drawbacks. Moreover, an efficient tracking system is necessary on the ground station. The elevation angle can be very high at any latitude (even high latitude) and in general is time dependent.

Satellite systems using MEO orbits show performance in between the two previously presented. At present, they are not used for telecommunication systems but for localization and navigation systems such as GPS (global positioning system) and the forthcoming GALILEO.

Satellites in HEO orbits travel over an ellipse, inclined 63.4° with respect to the equatorial plane, in which the Earth is located in one of the two focuses (Maral and Bousquet 2003). With respect to Kepler's law, satellites on this kind of orbit span equal areas in equal time intervals. As a consequence, they go very slowly around the apogee and appear almost fixed for users located at very high latitudes. Satellite handover, the Doppler effect, and the zoom effect represent the main drawbacks but are not as critical as in the case of LEO and MEO. Delay and FSL are comparable to GEO.

The different orbital configurations need not be used alone but can be combined to create a hybrid constellation. For example, a constellation can be composed of one or more satellites in GEO orbit and one or more satellites in LEO orbits. The two components can either be interconnected to reciprocally extend coverage or can be alternative points of access to improve availability (Luglio and Pietroni 2002).

Finally, although they are not satellites in the strict sense, high altitude platform stations (HAPS) are used for telecommunication purpose. They consist of special airships (blimps or aircraft) flying at about 20 km of altitude in the stratosphere, equipped with telecommunication payload to provide service over limited spot

areas (up to 200 km diameter). HAPS are conceived to operate in emergency situations (disaster or battlefield) or to provide extra capacity in hot spots from a fixed (or almost fixed) position in the space. From this point of view, they are assumed to be stationary, as GEO satellites but at any geographical position, and offering a high elevation angle (Tozer and Grace 2001; Karapantazis and Pavlidou 2005).

Space Segment

The space segment consists of the spacecraft, which contains a power section (batteries and solar panels), a stabilization and propulsion section (including propellant), a TT&C (telemetry telecommand and control) section to remotely control the spacecraft's on-board motors, and a payload section, which exploits communication functionality between two Earth stations. The payload architecture can be transparent if it acts as a bent pipe (just change the frequency and amplify signals) or it can be regenerative if it implements some on-board processing (OBP) features, which means that it must at least demodulate and remodulate signals, separating the uplink from the downlink. It can also code and decode signals, change polarization, interconnect beam to beam, route packets, and switch messages. On-board switching can be implemented at either base band or microwave frequencies.

Network Topology

The network topology concept in theory is independent of constellation characteristics but as a matter of fact applies only to geostationary systems.

Two kinds of topology are usually supported by a satellite network: star and mesh. The former consists of a central hub station and a set of user terminals, typically much smaller and less power consuming than the hub. The hub acts as the star center through which all the traffic transits; as a consequence, every pair of user terminals are physically interconnected through the hub, thus needing a double hop on the satellite, and thus maximizing delay and use of the bandwidth. In the latter topology, the user terminals can be directly interconnected among each other, needing only one hop on the satellite, thus minimizing the use of the bandwidth and delay (one hop). Hybrid configuration, with a subset of stations connected in full mesh mode and the others in star mode, is another possibility, which has trade-offs in performance.

Ground Segment

The ground segment is typically composed of Earth stations, a Network Operation Center (NOC) and a TT&C station.

The Earth terminals can be of two types: gateway and user terminals (Elbert 2000). Each terminal is equipped with a base-band section and a radio frequency (RF) section. The gateway, usually a big station, is in charge of connecting the satellite systems and the terrestrial networks. The user terminals represent the physical devices through which the users can directly access the satellite resources. They can be classified as fixed (very small aperture terminal, VSAT), transportable (VSAT-like, mounted on a vehicle but working in stationary conditions), or

mobile (handheld, cellular-like). VSAT terminals suitable to the mesh topology are more complex and expensive than those used for star networks.

The NOC includes the NCC (network control center) in charge of configuration management, capacity/bandwidth management, acquisition/synchronization control, performance management, alarm management, security management, billing, and accounting. The TT&C Earth segment exchanges information with the TT&C section on-board.

Physical Layer

The physical layer concerns the capability to establish, to ensure, and to keep physical connectivity, taking into account propagation channel characteristics, and the capability to generate power on-board. In fact, the propagation channel is characterized by meaningful nonlinearity that strongly affects technical choices.

Propagation Channel

Effects of the Troposphere. In the troposphere, the most relevant impairments on the transfer characteristic of the channel are:

- attenuation;
- increase of sky noise temperature;
- depolarization;

Above 18 GHz, especially with low elevation and/or margins, there are multiple sources of atmospheric attenuation (ITU-R 2001). Total attenuation (dB) represents the combination of four factors as shown in (1):

$$A_T(p) = \sqrt{(A_R(p) + A_C(p))^2 + A_S^2(p)} + A_G(p) \quad (1)$$

where

- $A_R(p)$ is the attenuation due to rain for a fixed probability (dB),
- $A_C(p)$ is the attenuation due to clouds for a fixed probability (dB),
- $A_S(p)$ is the attenuation due to tropospheric scintillation for a fixed probability (dB),
- $A_G(p)$ is the gaseous attenuation due to water vapor and oxygen for a fixed probability (dB),

being p the probability of the attenuation being exceeded in the range 50% to 0.001%.

The effects due to the troposphere can be significant (in particular for example at Ka band). For a link availability of 99.9% of the time, the total attenuation (including also gaseous attenuation) is over 6.2 dB at 20 GHz and is about 12 dB at 30 GHz and over 30 dB at 40 GHz for unavailability of about 0.1% of the time. To evaluate the rain margin, a detailed procedure is presented in ITU-R (2001).

Because rain attenuation represents the main factor impacting link availability, several fade countermeasure techniques have been proposed and will be briefly presented.

Methods to Counteract Rain Fading. Considering the randomness of the phenomenon and considering that heavy rain occurs only in limited time intervals and in limited areas, it can be quite wasteful to provide high power margins all the time to all the links over a certain coverage area. Thus, many methods have been proposed to counteract rain fading. Some of these use backup resources (bandwidth, power, equipment, etc.) only in those moments and for those links for which the attenuation becomes higher than a certain threshold.

A subset of these backup resources are based on a re-route strategy that operates on a “per link” basis (site diversity, orbit diversity) (Chung and Gallois 1993; Barton and Dinwiddy 1988). Most fade countermeasure techniques are based on reallocating a shared resource (bandwidth, time slots, power, etc.) for those links where fade occurs (frequency diversity, adaptive methods). Moreover, fade countermeasures can be classified in two groups: methods for improving outage probability, and methods for improving power margin (Carassa, Tartara, and Matricciani 1988).

Site Diversity. Site diversity consists in setting up two (or more) Earth stations (and the necessary terrestrial links), used alternatively (ITU-R 2001). The distance between stations is such as to minimize the joint probability of a rain event. Figure 1 shows the site diversity concept.

The advantage gained with site diversity must be traded for the noticeable disadvantage of setting up two antennas, two stations, and providing a terrestrial link between them.

Site Diversity with Shared Resource. With a more complex approach a set of stations share a set of backup stations. The gain obtainable with such a configuration depends on the distance among the stations, on the fading probability distribution on each station, and on the ratio between the number of main stations and the number of backup stations (Luglio et al. 2002). The ratio between the number of main stations and the number of backup stations can be optimized according to desired gain and costs. Figure 2 shows a configuration with ratio equal to two.

Orbit Diversity. Orbit diversity consists in using a backup spacecraft, normally used as a spare, to protect the link

Figure 1: Site diversity concept

Figure 2: Configuration of multiple site diversity with shared resource

against rain outages. The measured data indicates that rain attenuations on the two converging paths are highly correlated and that the improvement factor is trivial (≤ 1.2) (Lynn, Bergman, and Pursley 1980), unless high frequencies are used and high performance is pursued (Matricciani and Mauri 1995).

Up Path Power Control (UPPC). The negative effects due to rain fading on the uplink are compensated by increasing Earth station transmitted power, keeping the input power level of the satellite transponder constant (Chakraborty, Davarian, and Stutzman 1993). Although the Earth station would not work at maximum efficiency, the loss of downlink EIRP (Effective Isotropic Radiated Power) caused by a reduction in uplink power is eliminated (Willis and Evans 1988). The down link is weaker anyway, being unable to counteract rain fading. UPPC can easily be combined with other techniques (Chakraborty, Davarian, and Stutzman 1993).

Downlink Power Control. In case of multibeam coverage, with one station per beam and FDMA (frequency division multiple access) access, it is possible to introduce additional amplification in one (or more than one) beam in which the station requires assistance (Carassa 1987). This can be achieved with a variable gain power amplifier in each beam which allows reduction of the needed primary power.

A method similar to the one described above (variable gain on both links) that acts on power margin, is illustrated in Rautio (1980) and operates both on the uplink and on the downlink.

Repeated Transmission. In Chibisov (1987), a method based on repeated transmission of bursts, increasing signal to noise ratio, is presented. It is based on the fact that not all packages are subject to deep fading.

Burst Length Control (BLC). With Burst Length Control (applicable only in case of TDMA access), a set of time slots in the frame (shared resources) are left empty, with

the aim of improving the power margin (Carassa 1987). When the power margin for a given link becomes unable to overcome rain attenuation, the emission from/to the station in difficulty is increased in time H times, obtaining a multiplication by H of its energy and the possibility of introducing a proper coding on the signal. It is very easy to implement but it offers a small power gain, especially for high frequencies (Carassa, Tartara, and Matricciani 1988).

Adaptive Modulation. The aim is to keep constant the CNR (carrier to noise ratio) and the BER (bit error rate), dynamically changing the modulation scheme. In clear sky conditions, high spectral efficiency modulation — such as 16-PSK, 64-PSK or 256-QAM, — can be used. As a countermeasure, at the onset of the fade, a more robust modulation method is introduced, such as QPSK or BPSK. Using digital signal processing (DSP) in modems to accommodate different modulation methods, can reduce the spectral efficiency as the CNR (carrier to noise ratio) decreases (Gallois 1993).

Adaptive Forward Error Correction Coding (AFEC). Methods that use adaptive coding techniques can be applied as shared resource methods (Khan, Le-Ngoc, and Bhargava 1989). These techniques provide an additional margin, coding the information streams only during periods of link degradation. The coding is possible using backup time slots, in TDMA frame, which can be assigned to any user. The decision to do so can be taken on the basis of the received signal level or the BER. If there is no rain, the reserved time slots can be used by low priority traffic.

Adaptive Coding and Rate. A combination of two of the above techniques is proposed in (Ferro 1990). It consists in varying the transmission bit rate (from 8 kbit/s up to 1 Mbit/s) and the data coding rate (1, 7/8, 2/3, 3/4, 1/2) on a sub-bursts basis. When it is necessary to compensate high attenuation, coding redundancy is first of all incremented and then data rate is reduced.

Frequency Diversity. With frequency diversity, a higher band is used to carry most of the traffic and a lower band (typically a percentage of the former) is used to assist those links in certain time intervals during which rain attenuation overcomes a certain threshold (Figure 3). The result is an increment in outage probability for high frequency links with a consequent decreasing of the power margin to take in account in dimensioning the system, considering that at high frequencies also a small variation of outage probability yields a remarkable gain for the rain margin. The main impairments are, of course, the partial duplication of RF equipment and the need for cross strapping connection on-board.

Mobility. The second very important issue regarding propagation channel concerns mobility (the use of the user terminal while moving).

Two main overlapping phenomena must be taken into account: fast fading, due to multipath, and slow fading, due to shadowing. The former is due to refraction and reflection of the main ray over the surrounding environment while the latter is due to natural (mountains, hills, trees, etc.) or man made (buildings, bridges, etc.) obstacles. Both events depend on the environment and on the relative position user satellite; thus the analytical characterization must adopt the random process theory. The received signal assumes the following expression:

$$R(t) = z(t)s(t) + n(t) \quad (2)$$

where $z(t)$ and $n(t)$ are random processes. To evaluate the term $z(t)$ different models have been proposed in literature. The most general expression is:

$$Z(t) = S_1(t)(A + x_1(t) + j \cdot y_1(t)) + S_2(t)(x_2(t) + j \cdot y_2(t)) \quad (3)$$

where A is the (complex) LOS component, x_i, y_i ($i = 1, 2$) zero mean, independent Gaussian (fast fading) r.v.s. and S_i lognormal (shadowing) r.v.s. The other models can be derived from the generalized expression suppressing the factors not applying to the particular selected scenario (Corazza and Vatalaro 1993).

Satellite Diversity. Satellite diversity consists in utilizing more than one satellite to increase the number of paths between the hub and the user terminal in order to either improve E_b/N_0 or link availability, thus counteracting shadowing. The diversity order can be theoretically arbitrary (depending on constellation architecture) but in practical systems dual diversity is implemented (Loreti and Luglio 2001).

Link availability can be increased as compared to the case of a single link, being the joint probability in general lower than the single case. The advantage achieved by using diversity depends on the constellation structure and on the azimuthal correlation among links. Several propagation models applicable to diversity scenario have been developed (Loreti and Luglio 2001).

Modulation, Coding, and Interleaving

With regard to modulation, phase modulation schemes are usually adopted due to their intrinsic robustness to a non-linear channel. The most used scheme is QPSK (Quadrature Phase Shift Keying), but in particular cases even higher order modulations are used (see DVBS-2).

Channel encoding introduces redundancy to protect signals against errors. In satellite communications, concatenated coding is often adopted to counteract

Figure 3: Frequency diversity concept

both burst errors and random errors. For example, the DVB-S (digital video broadcasting satellite) (European Telecommunication Standard Institute 1997) standard adopts Reed Solomon block coding (204,188) to combat burst errors and convolutional coding (adaptive rate from 1/2 up to 7/8) to combat random errors. Also, turbo codes have actually been used in recently launched systems (Giancristofaro et al. 2000).

Interleaving, used to combat channel fluctuations resulting from multipath, aims at randomizing bit errors to change burst errors in random errors. It consists of rearranging the order of a sequence in a deterministic way and then rebuilding the original sequence (Luglio et al. 1997). The bits can be arranged in a row of a matrix and transmitted in columns. Either block or convolutional interleaving can be implemented.

Antenna Coverage Pattern

The coverage strategy can significantly affect the physical layer. Multibeam coverage improves spatial selectivity (allowing frequency reuse) and gain, which allows less critical user terminal design and uneven power distribution at the price of increasing complexity and costs (Loreti, Luglio, and Palombini 2000).

Interference

Another impairment, mainly resulting from multibeam coverage, is the intrasystem co-channel interference (Vatalaro et al. 1995; Caini et al. 1992; Loreti and Luglio 2002). It arises from the overlapping of several side lobes of the interfering beams with the main lobe of the interfered beam. If every beam uses the same frequency (CDMA), the overlapping of two main lobes can also cause serious interference. In satellite systems, co-channel interference is more critical than in terrestrial cellular networks. In fact, for terrestrial systems, morphology and man-made buildings sometimes isolate adjacent cells and zones, allowing a more significant use of frequency reuse.

Interference Countermeasures. Some of the most effective interference reduction techniques at system level are described in Loreti and Luglio 2002 and listed below. The first two are peculiar to LEO and MEO systems, while the others can also provide meaningful results if implemented in GEO systems.

- A. beam/cell turnoff;
- B. intraorbital plane frequency division;
- C. interorbital plane frequency division;
- D. use of two orthogonal polarizations;
- E. power control;
- F. position dependent frequency assignment;
- G. frequency hopping;
- H. multi-user detection;
- I. dynamic resource allocation;
- J. optimum bandwidth (or code) assignment.

OBP Capabilities

OBP (on-board processing) consists of the payload's capability to at least demodulate and remodulate signals. It can greatly improve the link design because

isolating uplink and downlink avoids direct transfer of noise accumulated on the uplink to the downlink. Furthermore, it achieves better performance in terms of the E_b/N_0 required, reduced power needed on both links, and reduced intermodulation.

MAC Layer

FAMA (Fixed Assignment Multiple Access) Techniques

In general, the same multiple access techniques developed and implemented on terrestrial systems are adopted. In particular, the classical orthogonal techniques are used: FDMA (frequency division multiple access), TDMA (time division multiple access), and CDMA (code division multiple access) or hybrid schemes such as MF-TDMA (multifrequency TDMA). FDMA can be implemented in different schemes: SCPL (single carrier per link), SCPS (single carrier per station), and SCPC (single carrier per channel). Each scheme performs differently in terms of efficiency and generation of intermodulation products. The use of TDMA, which is more flexible than FDMA, requires a critical synchronization system that takes into account the variance of the propagation delay, which must also be carefully considered in the design of the guard time slots (Maral and Bousquet 2003). CDMA allows full frequency reuse, satellite soft handover, satellite path diversity exploitation, and application of interference mitigation techniques such as multi-user detection (MUD) (De Gaudenzi and Giannetti 1998).

RA (Random Access) Techniques

RA (Random Access) techniques are based on the concept that each user starts transmitting when a packet is available. Because no coordination among stations is implemented, packets may collide. In the Aloha scheme, every station monitors its transmission and detects eventual collisions after an RTT or round trip time, which is ~270 ms if the management is on board or ~540 ms if the management is on the ground. Collided packets are retransmitted after a random delay. Efficiency is low. The slotted Aloha scheme improves performance in terms of efficiency, introducing the concept that packets are transmitted in time slots. Also, Selective Reject Aloha improves efficiency, taking advantage of partial collisions and allowing the retransmission of only the overlapped portion, of course, at the price of increased overhead. Finally, if packets are spread either with a PN sequence or in time, the effect of collisions is weakened.

DAMA (Demand Assignment Multiple Access) Techniques

With DAMA techniques, resources are assigned on the basis of requests. Most of these techniques share resources in the time domain. Resources can be reserved either explicitly (for a given number of time slots) or implicitly (a source occupies a certain slot until its transmission is over). Contention is limited to access times. At steady-states it virtually works as a TDMA system.

Techniques based on the PRMA (packet reservation multiple access) concept can be considered. To achieve significant efficiency, these techniques require a frame

length longer than RTT (round trip time). Thus, they seem more suitable for systems in LEO orbit (Del Re et al. 1997)

DAMA protocols implemented in TDMA networks are very important and worth mentioning. In particular, in DVB RCS standard (European Telecommunication Standard Institute 2000) five different methodologies are applicable:

a) Continuous Rate Assignment (CRA)

The resources are negotiated between RCST (return channel on satellite terminal) and NCC for all the superframes in the period. Static capacity is assigned at the beginning of the communication. No BoD (Bandwidth on Demand) delay is experienced; low efficiency is achieved.

b) Rate Based Dynamic Capacity (RBDC)

The RCST dynamically requests capacity to NCC. Capacity is assigned after explicit request and the request expires every two superframes (by default). It aims to equal input and output transmitter buffer rate. Suitable for VBR (variable bit rate) traffic tolerating MSL (Minimum Scheduler Latency, delay introduced by the scheduler to generate the Burst Time Plan or BTP). RBDC and CRA can be jointly used (CRA ensures a fixed allocation and RBDC ensures a variable assignment for no real-time applications). It represents a trade-off solution.

c) Volume Based Dynamic Capacity (VBDC)

The RCST dynamically requires a volume of traffic with requests being cumulative and NCC satisfies the requests. It represents a best-effort service: capacity requests aiming to empty the buffer. It is characterized by high BoD delay (RTT~1.6 s) and high efficiency.

d) Absolute Volume Based Dynamic Capacity (AVBDC)

The requests are absolute and not cumulative as in the previous case.

e) Free Capacity Assignment (FCA)

No signaling between NCC and RCST is foreseen. Free capacity that would otherwise be wasted is automatically assigned not according to any associated traffic profile (random assignment).

Other DAMA techniques are also proposed in (Zhang 2003).

Hybrid Techniques

Hybrid techniques, combining fixed, DAMA and random assignment are also proposed in (Zhang 2003).

Network Layer

Network issues are applicable whenever routing operations are foreseen in the satellite link. Two approaches can be adopted: connection-oriented or connectionless. The latter approach is compliant with IP (Internet protocol). Moreover, the use of IP protocol well suits multicast management, and, as in a terrestrial network, connectionless networks offer some degree of fault tolerance for data delivery. Against this approach, satellite networks (referring to LEO systems) may be too dynamic

for standard IP routing and Internet-style routers may require too much memory (perhaps not compatible with the limited space on-board). Among the other problems with using IP, the TTL (time-to-live) and IP packet fragmentation are emphasized because of the huge delay (Partridge and Shepard 1997).

Present satellite networks that provide multimedia wideband services offer an IP interface, managed at ground facilities. The use of regenerative payloads able to perform network-layer functionality in space can offer the opportunity to more efficiently manage satellite networks.

Transport Layer

TCP (transmission control protocol) is the layer 4 protocol which ensures reliable end-to-end communication implementing the concept of acknowledgement of received data. When the path includes a satellite link, this mechanism severely impacts performance due to the high propagation delay. To mitigate such impairments, several countermeasures can be implemented at the transport layer.

TCP Performance

Transmission Control Protocol (TCP) is based on the mechanism of the sliding window which increases exponentially during the Slow Start phase until the Slow Start Threshold is reached, and then linearly during the Congestion Avoidance phase. The high latency implies that it takes a long time to reach the optimum window size, while a high packet loss can be experienced as a consequence of the meaningful BER in particular channel conditions. Furthermore, when the satellite provides wide band access, the bandwidth x delay product becomes very large, impacting the ramping time (Stevens 1994).

TCP Performance Improvement

Several techniques have been proposed to mitigate impairments caused by delay (Allman, Glover, and Sanchez 1999; Border et al. 2001; Loreti et al. 2001; and Luglio et al. 2004). Some of them are specifically designed for satellites, while others are for more general environments. Many proposals are based on modification of the flow control (e.g., enlarging the dimension of the initial window, or reducing the number of acknowledgments) and of the recovery mechanism (dynamic estimation of the available bandwidth, etc.); others are based on modification of the architecture (e.g., splitting the path, terminating the connection at each step, and acknowledging packet reception). Among the latter type of solutions, some adopt standard algorithms or modified versions, and there are solutions typically known as accelerators, which are implemented in real systems and based on proprietary standards.

Application Layer

There is no real limitation to providing any service through a satellite network. Every kind of service and relative applications can be implemented but in some cases, performance may not be optimum. In fact, the propagation delay affects performance of real-time interactive services

(e.g., voice, videoconference) but, on the other hand, the suitability to multicast operation makes satellite systems more efficient and cost effective. In particular, both real-time and store and forward services, both fixed and mobile services, both narrow band and wideband services, as well as unicast, multicast, and broadcast services are currently provided.

Payload

The payload represents the portion of the space segment in charge of exploiting telecommunications functionality in the strict sense. The payload receives the signal from the Earth stations and radiates it back after having processed it, at least in terms of converting carrier frequencies and power amplification (transparent) or implementing demodulation and remodulation, decoding and coding and several other processes (regenerative or OBP). The transmission/reception function is exploited through on-board antennas which can be either single beam or multibeam. In terms of OBP capabilities and of coverage strategy, payload architecture can be definitively classified as in Figure 4. The arrows show the possible combinations: in fact payloads can be transparent and single beam, regenerative and multiple beams, or transparent and multiple beams. In particular, from the point of view of technology, payloads evolved from transparent single beam to transparent multiple beams, thanks to the capability of accommodating larger antennas on-board that are automatically deployable and to the use of higher frequencies, then they further evolved to regenerative payloads, thanks to the capability of implementing OBP on-board.

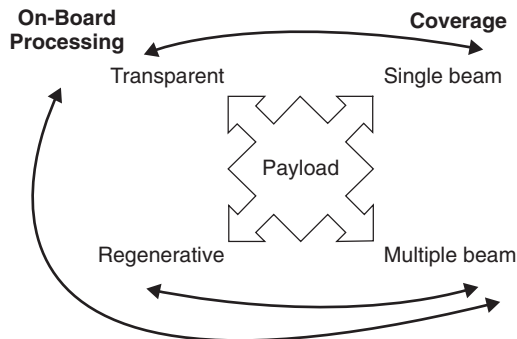

Figure 4: Payload architecture classification

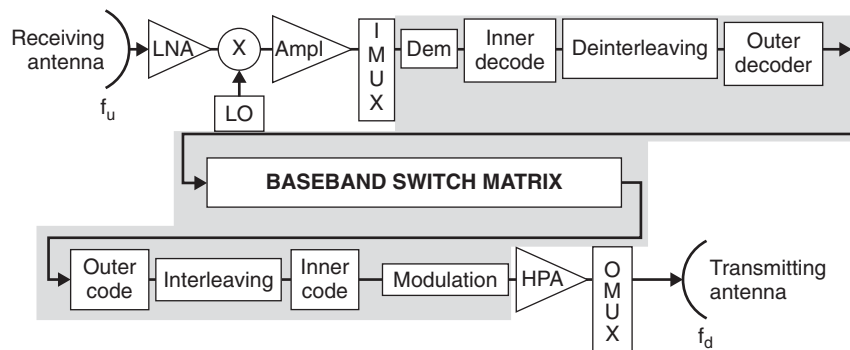

Figure 5: Payload transmission chain

The general scheme of a payload including OBP capabilities is shown in Figure 5. After the receiving antenna, a low noise amplification stage (LNA) provides the first amplification before a local oscillator (LO) down converts the signal to IF (intermediate frequency) or baseband and a demultiplexer (IMUX) disaggregates different contributions. In the eventual OBP section, the signal is demodulated, then decoded in three different stages (inner convolutional, deinterleaved and then outer Reed-Solomon) as in the case of DVB standard. Then a baseband switch matrix switches signals from beam to beam before it is again coded and modulated. Finally, after a high power amplifier (HPA) stage and an output multiplexer (OMUX) the signal is transmitted down to ground station through the transmitting antenna. The basic architecture of transparent payload can be carried out by removing the OBP chain (grey area) (Maral and Bousquet 2003). A payload can even partially implement the depicted transmission chain. Complexity and weight increase due to the presence of more hardware.

When the coverage is achieved by multibeam antennae, the connectivity between any pair of beams must be ensured. (Reduced connectivity patterns can be allowed.) The interconnection pattern is decided during the design phase on the basis of traffic forecasts. The interconnection between a pair of beams can change using switches controlled by telecommand, pre-recorded sequence, or switch matrix. Very fast reconfiguration may be required (on the order of a few hundreds of nanoseconds). To this aim, active switching elements (PIN diodes), optical switching, or a microwave switching matrix is required.

In case of MF-TDMA discipline, the switching matrix architecture can work with either the T-S-T (time-space-time) approach or the S-T-S (space-time-space) approach (Selenia Technical Review 1990).

Standards

Satellite systems are mostly based on proprietary standards, both in terms of hardware and services. Nevertheless, in the last years some standards have been developed for broadband services, both fixed and mobile. More emphasis will be placed on the former due to its much greater commercial impact.

DVB-S (Digital Video Broadcasting Satellite) and DVB-S2

The DVB (digital video broadcasting) standard was issued in 1997 for broadcasting services (European Telecommunication Standard Institute 1997). At present it includes standards for terrestrial fixed (DVB-T), for terrestrial mobile (DVB-H for handheld terminals), cabled (DVB-C), and satellite systems (DVB-S evolved into DVB-S2 and the forthcoming DVB-SH, adaptation of DVB-H to satellite handheld terminals). The DVB-S (DVB satellite) standard regulates broadcasting of signals in digital format and how they must be processed before being transmitted. Two basic operations are regulated: base-band processing and satellite channel adaptation.

The base-band processing concerns the adoption of MPEG-2 (Moving Picture Expert Group-2) as the source coding technique on different source signals (video, audio, and data); the following (not mandatory) packetization of data of a single program into packetized elementary stream (PES); and the final multiplexing of a number of PES into the MPEG-2 transport stream (TS). The different data elements can carry independent timing information. In this way, audio information can be synchronized with video information in the receiver, even if they do not arrive aligned at the receiver, which allows the transmission of conventional television programs.

The satellite channel adaptation concerns the types of modulation and coding schemes to be adopted to meet the target quality of the signal (Bit Error Rate around 10^{-11}).

The processes involved in this adaptation are transport multiplex adaptation and randomization for energy dispersal, outer coding (i.e., Reed-Solomon), convolutional interleaving, inner coding (i.e., punctured convolutional code), base-band shaping, and modulation. The randomization is applied to make the RF spectrum approximate a white noise process. The channel coding is applied through three steps: outer code Reed-Solomon (204, 188, $T = 8$), convolutional interleaving with the aim of randomizing burst errors, and convolutional coding with a variable code rate (1/2, 2/3, 3/4, 5/6, and 7/8). Gray-coded QPSK modulation with absolute mapping (no differential coding) is adopted. Base-band signal is square-root-raised-cosine-filtered with a roll-off factor of 0.35.

The DVB approach offers a good degree of flexibility. A 38 Mbit/s data flux can contain eight standard definition television (SDTV) programs, four enhanced definition television programs (EDTV), or one high definition television (HDTV) program, all with associated multichannel audio and ancillary data services. The maximum data rate for a data stream is typically about 38 Mbit/s accommodated in a 33-MHz satellite transponder.

Recently, the DVB-S standard was updated in the DVB-S2 version. In the new scheme, which modifies the satellite channel adaptation block only, adaptive modulation and coding (ACM) have been introduced. In particular, low density parity check codes (LDPC) have been selected with Bose–Chaudhuri–Hochquenghem (BCH) code-block length 64,800-bit (or 16,200-bit) periodic structures that facilitate parallel decoding with about 50 decoding iterations. Available coding rates are 1/2, 3/5, 2/3, 3/4, 4/5, 5/6, 8/9, and 9/10. Moreover, five modulation formats, all optimized to operate over nonlinear transponders, have been selected: BPSK (1 bit/s/Hz), QPSK (2 bit/s/Hz), 8PSK

(3 bit/s/Hz), 16APSK (4 bit/s/Hz), and 32APSK (5 bit/s/Hz). Then, three roll-off factors are allowed: 0.35, 0.25, and 0.20 (DVB-S: only 0.35). With the new standard, an optimization of spectral resources in the order of 30–40% is estimated. If confirmed, the satellite may be more competitive in terms of costs with terrestrial services such as ADSL (asymmetric digital subscriber line).

DVB RCS (DVB Return Channel on Satellite)

The success of the DVB standard due to its capability of transmitting huge quantities of data in a very flexible way, with consequent availability of low-cost technology, extends its field of applicability beyond the transmission of TV signals only. In addition, the compatibility with IP protocol allows processing of the IP packet in the DVB stream. As a consequence, first the use of DVB for one-way systems (DVB IP with return channel on terrestrial networks) has been introduced. The data are received through the same equipment (antenna and receiver) used for digital TV, but the equipment is connected to a PC with a suitable decoder. Then, a two-way standard based on DVB was recently introduced, with return channel on satellite (DVB RCS), which allows bidirectional communications up to 2 Mbit/s in the return link and shares the bandwidth on a MF-TDMA discipline (European Telecommunication Standard Institute 2000). The user terminal is very similar to the receiving equipment but with a RF front-end working at 1–4 W. The great success and market penetration of this technology is leading researchers and standardization bodies to extend the use of DVB RCS for mobile services. Specifications are expected to be issued in 2008.

S-UMTS (Satellite–Universal Mobile Telecommunication System)

Another standard that has been evaluated by ETSI concerns the satellite component of the UMTS [universal mobile telecommunication system] (Caire et al. 2002). SW-CDMA (satellite wideband CDMA) aims to ensure the maximum degree of compatibility with the W-CDMA (wideband CDMA) conceived for the terrestrial component. It is very similar to the ETSI UTRA proposal and is suited to the specific satellite environment. The main features are: wide range of bearer services (from 2.4 kbit/s up to 144 kbit/s), power and spectral efficiency achieved through path diversity exploitation, coherent demodulation on the return link, multiuser detection scheme, overhead reduction using common pilot/beam approach, and compatibility with adaptive antenna systems. Moreover, user localization capabilities are implemented. Two bit-rate options are supported: 4.096 Mbit/s (frame duration = 10 ms) and 2.048 Mbit/s (frame duration = 20 ms). QPSK and dual-BPSK (for low data rate) modulations are adopted. The use of scrambling code is optional.

STANDARDIZATION, REGULATION, AND SPECTRUM ALLOCATION

Standardization Bodies and Related Activities

Several standardization bodies are in charge of developing standards as well as related issues of interest for satellite

systems. The main worldwide based institutions are listed here:

- IEEE (Institute of Electrical and Electronic Engineers) (<http://www.ieee.org>)
- ITU (International Telecommunication Union) (<http://www.itu.int>)
- ISO (International Organization for Standardization) (<http://www.iso.org>)

Some others are of regional interest such as:

- CEPT (European Conference of Postal and Telecommunications) (<http://www.cept.org>)
- ETSI (European Telecommunications Standardization Institute) (<http://www.etsi.org>)
- FCC (Federal Communications Commission) (<http://www.fcc.gov>)
- The Telecommunication Technology Committee (<http://www.ttc.or.jp>)

In addition to the above mentioned bodies, fora of interest are:

- IETF (Internet Engineering Task Force) (<http://www.ietf.org>)
- GSC (Global Standards Collaboration) (<http://www.gsc.etsi.org>)
- AIS (Alliance for the Information Society) (<http://www.eubusiness.com>)
- MMAC (Multimedia Mobile Access Communication Systems) (<http://www.arib.or.jp/mmae>).

ITU surely represents the most interesting, with both the Radiocommunication sector and the Telecommunication sector. As concerns the former, the most relevant study groups are:

- SG4 Fixed-Satellite Service (Systems and networks for the fixed-satellite service and inter-satellite links in the fixed-satellite service, including associated tracking, telemetry and telecommand functions).
- SG6 Broadcasting Service — terrestrial and satellite (Radiocommunication broadcasting, terrestrial and satellite, including vision, sound, multimedia and data services principally intended for delivery to the general public. Production and radiocommunication, including the international exchange of programs as well as the overall quality of service.)
- SG8 Mobile, Radiodetermination, amateur and related, Satellite Services (Systems and networks for the mobile, radiodetermination and amateur services, including related satellite services).

As concerns the telecommunication sector, the most relevant group is:

- ITU-T Study Group 13 (Next Generation Networks).

In the frame of ITU-R the WRC (World Radiocommunication Conference) is in charge to review, revise the Radio Regulations, the international treaty governing the use of the radio-frequency spectrum and the geostationary-satellite and non-geostationary-satellite orbits.

The agenda determined by the ITU Council takes into account recommendations made by previous world radiocommunication conferences. The general scope of the agenda is established four to six years in advance, and the final agenda two years in advance.

Spectrum Management and Coordination

Spectrum management is a combination of technical and administrative procedures aiming at enabling radio stations everywhere to operate on interference-free frequencies and without causing interference to other stations. It is implemented at two levels: national and international. The procedures are described in the Radio Regulations.

Coordination consists in bilateral negotiation to achieve an agreeable arrangement on the use of shared frequency bands. The procedures for coordination of space communication systems are established in the following provisions of the Radio Regulations (RR):

Article 11: Three main procedures of coordination

- Geostationary satellite network with other networks
- Earth stations with stations for terrestrial services
- Transmitting terrestrial stations with Earth stations

Resolution 46 (WRC 95):

- Non GEO systems and GEO in certain frequency bands (the difference in the determination of the need to coordinate)

Article 7 of Appendix 30:

- Fixed satellite services in the bands 11.7–012.2 GHz (Reg 2), 12.2–12.7 GHz (Reg 3) and 12.5–12.7 GHz (Reg 1) for broadcasting

The required data to be supplied at the initial coordination stage is described by a single regulatory text in the RR: Appendix S4.

Spectrum Allocation

Spectrum allocation is performed by ITU-R and in particular by the World Radiocommunication Conference. Table 1 shows, as an example, the allocated bandwidth for ITU region 2.

Different allocations can be adopted in different regions for some sub-bands. In case a global service must be provided simultaneously in more than one region (or even globally) and no common band is allocated for all the regions, a specific decision must be adopted by WRC, as in the case of Iridium and Globalstar systems.

Table 1: Spectrum Allocation for Satellite Services

	Band	Uplink	Downlink
	C	5,925–6,425 MHz 7,900–8,400 MHz	3,700–4,200 MHz 7,250–7,750 MHz 10.95–11.2 GHz
Fixed services	Ku	13.75–14.5 GHz	11.45–11.7 GHz 12.5–12.75 GHz
	Ka	27.5–30 GHz 30–31 GHz	17.7–20.2 GHz 20.2–21.2 GHz
	UHF	148–150.05 MHz	137–138 MHz
	L	1,626.5–1,660.5 MHz 1,610–1,626.5 MHz	1,525–1,559 MHz 2,483.5–2,500 MHz
Mobile services	S	2,170–2,200 MHz 2,655–2,690 MHz 7,900–8,025 MHz	1,980–2,010 MHz 2,500–2,535 MHz 7,250–7,375 MHz
	Ka	29.9–30 GHz 30–31 GHz	20.1–20.2 GHz 20.2–21.2 GHz

Table 2: Integration Levels

1	Geographical	Satellite provides service only in areas not covered by terrestrial networks; services and technologies can be different.
2	Services	Implies geographical integration and compatibility among services provided by the two networks; performance can be different.
3	Network	Same procedures and protocols allowing the same number to be dialed independently on the terminal; different carrier frequency eventually used by the two segments must be taken into account.
4	Equipment	Compatibility in terms of access, protocols, data rate; at least a part of the circuits could be shared.
5	System	Maximum level; users are not aware of what kind of connection has been established.

INTEGRATION WITH TERRESTRIAL SYSTEMS

Satellites, if used as stand-alone systems, have a limited range of application implying limited market penetrability and appeal. On the other hand, integration with terrestrial networks must be pursued both to reciprocally improve performance (satellite can complement terrestrial network and vice versa) and to gain meaningful market segments.

The use of satellite systems as an overlay network of several different terrestrial networks can represent a meaningful field of application and an interesting market segment. In fact, satellite can work as a backbone among Wi-Fi or WiMax cells, can act as a gap filler between two cells that are not contiguous, or can even extend coverage for those networks usually implemented only in hot spot areas (Luglio, Mazzenga, and Corazza 2006; Giuliano et al. 2006). In addition, satellite systems can allow ad hoc networks, usually used in very limited areas, to access very far away telecommunication networks

(for example, remotely located civil protection head-quarter) (Luglio et al. 2006).

In this scenario, recommendation ITU-R M.1182-1 (ITU-R 2003) identifies five levels of integration between satellite and terrestrial systems for interoperability, as shown in Table 2, where the five levels are listed and described in some detail.

CONCLUSION

Satellite systems and technology represent a valuable possibility of improving efficiency to provide telecommunication services in a computer network. Satellites can be used as stand-alone systems where terrestrial facilities are not present, when they are damaged or destroyed, or in locations where they are not economically feasible.

The basic characteristics of satellite networks have been presented, highlighting both physical aspects and network layer aspects. Interoperability with terrestrial systems has also been addressed.

GLOSSARY

- Broadcast:** A connection allowing information transfer from one to everybody.
- Coverage Area:** The area on the Earth's surface over which the signal-to-noise ratio in both up- and down-link for a user located inside is greater than the minimum required ratio.
- Forward Link:** The link from the hub station to the user terminal.
- Gateway:** The Earth station of a satellite system that ensures connection to terrestrial networks.
- Global Information Infrastructure:** The concept of a unique telecommunication infrastructure at planetary level to provide services everywhere to everyone.
- Interference:** Portion of the received power originating from unwanted source.
- Multicast:** A connection allowing information transfer from one to many.
- Multiple Access:** A regulated exploitation of a common resource by different users distributed at different locations.
- Payload:** Subsystem of a satellite spacecraft in charge to implement telecommunication functions.

THE LAND-MOBILE SATELLITE CHANNEL

Mobile satellite systems provide many services to aeronautical, maritime, vehicular (automobiles, trucks, trains), and pedestrian communications (handheld telephones). Land-mobile satellite communication usually refers to vehicular and pedestrian communications only and, as such, is a very important field of application, development, and research. Land-mobile satellite systems, however, need to be integrated with terrestrial mobile and fixed networks to optimize the overall benefits for both users and network operators (Pattan 1998).

Land-mobile satellite channels can be degraded much more seriously than fixed-satellite channels because electromagnetic waves propagate in a high hostile environment, together with the necessity of using small, simple, and low-cost antennas and receivers. The antennas are broad beam with low gain, resulting in a low sensitivity receiver. The physical environment may consist of obstructions, such as buildings and trees, that can cause multipath and severe signal attenuation and make the reception of signals of tolerable quality very difficult.

Land-mobile satellite links need to operate in the greatest variety of radio propagation conditions. At one extreme, there are open stretches of road with direct visibility to the satellite, and, at the other, there are the heavily shadowing environments of cities. At frequencies above 10 GHz, the channel may also be affected by large tropospheric fading.

Land-mobile satellite channels, as terrestrial mobile channels, are affected by multipath fading and shadowing. These phenomena are extremely important because they determine the distribution of the received power as long as tropospheric effects are not yet important. Moreover, compared to terrestrial outdoor mobile receivers, a mobile satellite receiver can receive a strong direct or specular component (if the receiving antenna is not very directive), which is essential to the line-of-sight link power budget but modifies significantly the channel statistics. Another characteristic of land-mobile satellite

channels is the dependence of the propagation characteristics on the satellite orbit (Loo and Butterworth 1998; Lutz et al. 1991; Wu et al. 1994).

Satellite orbits can be geostationary (GEO), orbits in the equatorial plane at an altitude of 36,000 km, or nongeostationary (Pattan 1998). The orbit of nongeostationary satellites can occur in planes with arbitrary inclination and altitude, although the most used are low-altitude Earth orbits (LEOs; 500 to 1700 km), medium-altitude Earth orbits (MEOs; 5000 to 10,400 km), or highly elliptical orbits (HEOs; apogee around 40,000 to 50,000 km, e.g., Molniya and Tundra orbits; Pratt, Bostian, and Allnutt 2003; Maral and Bousquet 1998). Nongeostationary satellites are never seen, of course, as stationary by a mobile (or fixed) user because the satellite changes its elevation angle and slant range continuously as it crosses the sky. Therefore, the propagation channel conditions vary largely, and a strong Doppler frequency shift can appear. This is the apparent change in frequency of the transmitted signal (both in carrier frequency and symbol rate) due to the relative motion of the mobile and transmitter.

The frequency bands allocated to land-mobile satellite communications are contiguous to those allocated to the terrestrial networks so that no major differences are observed in the nature of the physical phenomena affecting radiowave propagation, but only in their intensity and time dependence. The frequency bands of the actual land-mobile satellite communications are L band (1.5 GHz) or S band (3 GHz), for example, the Globalstar system (satellites orbiting at about 1400 km; Dietrich, Metzen, and Monte 1998). At these frequencies the interaction of electromagnetic waves with the troposphere (tropospheric effects) is negligible, compared to the interaction with orography, buildings, trees, and other obstacles.

The large bandwidths allocated at K_u (12/14 GHz) and K_a (20/30 GHz) bands and the availability, today, of a mature technology for these frequency bands have made them more attractive for broadband multimedia services. However, when compared to mobile channels working at the lower frequency bands, K_u and K_a band land-mobile satellite channels face a much more hostile

propagation environment and show their own unique propagation characteristics. Besides suffering the same propagation impairments of L and S bands, new impairments are measured because of the troposphere constituents—mainly rain, although rain attenuation can be statistically less severe for a vehicle than for a fixed receiver if the vehicle is driven in a straight line.

K_u and K_a band land-mobile channels suffer from more severe shadowing and faster multipath fading. The time variation of the multipath fading is directly related to Doppler effects, described by the Doppler power spectrum of the channel or by its reciprocal (coherence time of the channel), and these effects are more serious at K_a band because the electromagnetic wavelength is shorter than that at L, S, and K_u bands, so that constructive and destructive interference-producing multipath fading is much faster and the channel correlation time is much shorter.

Land-mobile satellite channels are usually required to use adaptive power control between the mobiles and the satellite. In the cases of time or frequency orthogonal systems, such as time-division multiple access (TDMA) or frequency division multiple access (FDMA), the main purpose of power control is to maintain a constant average quality for all users and to minimize the required transmit power. In a direct-sequence code division multiple access (CDMA) system, accurate adaptive power control is critical for a good overall system performance because the multiple-access users act as interferers to each other (Maral and Bousquet 1998; Pratt, Bostian, and Allnutt 2003).

The traffic flow through the terminal can be low but it has to pay for the full connection regardless. To be competitive, the size, cost, and power consumption of a land-mobile channel should approach those of the terrestrial mobile (cellular) channels, and it should be possible to connect it with the terrestrial system. The transmitted power should conform to radiation safety standards.

The signal-to-noise ratio of a land-mobile satellite channel fluctuates rapidly because of multipath fading (small-scale fading). The fading on the uplink is usually uncorrelated with that on the downlink, since the uplink and downlink frequency bands are separated by more than the coherence bandwidth of the channel. The signal may also suffer large-scale and more slowly varying shadowing losses due to blockage by buildings, hills, and trees, which are usually assumed identical on the uplink and downlink.

There are severe and practical constraints imposed on the design of a mobile terminal. The limited mounting space on vehicles largely restricts the antenna size, so that the achievable gain is low. The antennas used for the land-mobile satellite communications are similar to those used for terrestrial mobile communications in the same frequency bands, but with more demanding features and higher costs. Whether geostationary satellites are employed or not, the mobile Earth terminal may need a directional antenna, and this component can be critical because the directional beam must be dynamically oriented toward the satellite in a very rapidly changing environment.

One of the benefits of the K_a band is higher antenna gain and a substantial reduction of its physical size compared to the antennas of the lower-frequency bands.

To achieve these benefits it is necessary, however, to overcome higher component losses and design a more accurate and demanding satellite-tracking system to take care of the narrower antenna beam. Both parabolic (Densmore and Jamnejad 1993) and microstrip antennas (Telikeypalli et al. 1995) can be used, the latter more suited to conform to vehicle surface. The antenna system has to be rugged enough to withstand the shock and vibration of the mobile vehicle; it has to complete a full azimuth search and acquire the satellite signal within a few seconds; it has to track the satellite by compensating for vehicle yaw, pitch, and roll-up; and the tracking system should not lose track of the satellite direction during signal outages (it must rely on inertial pointing during such periods).

Whenever user terminals are mobile, it is necessary, of course, to manage their mobility so that calls can be established efficiently. To minimize call setup time and network signaling requirements, and to improve the call setup success rate, the terminal or the network must estimate the user's position. Furthermore, in a LEO or MEO satellite system the signal level may deteriorate when a connecting satellite moves out of range or is temporarily not visible because of an obstruction. Handover increases the complexity of a network, and, in general, the number of handovers decreases as the satellite orbit altitude increases because the orbit period increases too. For a LEO system, the satellite visibility is of the order of few minutes; for a MEO system, it is of the order of an hour; and for a GEO system, it is exactly twenty-four hours and no handover is needed.

The modulation schemes most often used in mobile communications are the classical binary phase shift keying (BPSK) and quadrature phase shift keying (QPSK). The carrier (BPSK) or the two orthogonal carriers (QPSK) are modulated in amplitude, double side bands, by positive and negative pulses. The carrier is suppressed to save power, and, as a consequence, the receiver has to use coherent demodulators that need to recover both the frequency and phase of the carriers in a hostile environment with significant Doppler frequency shift, especially in LEO systems. Other modulation schemes used in terrestrial mobile communications are also considered for the land-mobile satellite communications (Pattana 1998).

Depolarization must be considered whenever two orthogonal electromagnetic waves are used to increase channel capacity without increasing the bandwidth requirements, a technique known as *frequency reuse* and already applied to satellite television broadcasting at K_u band. As depolarization alters the polarization properties of the incident wave, linear and circular polarizations are transformed into elliptical polarization, and the polarization axes themselves may be rotated. As a consequence, depolarization produces interference between the two orthogonal channels and degrades system performance by reducing the effectiveness of frequency-reuse techniques.

Forward error correcting (FEC) codes are used for channel coding, as they are for mobile terrestrial communications (Hagenauer and Lutz 1987; Pratt, Bostian, and Allnutt 2003). The satellite land-mobile channel may experience error bursts due to multipath reflections and shadowing, or to rain attenuation, so that Reed-Solomon codes, concatenated with convolutional codes, are

preferred because they can correct these kinds of errors. Very efficient codes are the so-called “turbo” codes that represent the most significant advance in concatenated coding, with performance approaching the Shannon limit. Turbo codes combined with a channel interleaver can combat fast multipath fading and can also be combined with techniques that combat severe slow fading due to shadowing, rain, or other atmosphere constituents. Other important codes are the low-density parity check (LDPC) codes (Gallager 1963), rediscovered ten years ago (MacKay and Neal 1996) and now likely to become the standard in error correction for applications from cell phones to interplanetary communication.

The diversity schemes used for terrestrial mobile communications can also be applied, in general, to land-mobile communications, but they have to be adapted to the highly variable propagation characteristics and to the terminal receiver.

Diversity schemes can be more effective in clear-sky conditions than in the presence of precipitation because distortions change largely only in few wavelengths (fast fading due to multipath). Antenna (and polarization) diversity can combat the fast fading due to multipath by placing two antennas at a distance of several wavelengths—an architecture that can be, of course, implemented on a vehicle.

However, when rain attenuation affects the land-mobile channel, as rain attenuation is significantly correlated over several minutes and hundreds of meters, the only diversity scheme that may be used (disregarding the trivial method of largely reducing the bit rate and thus the information rate), both in the uplink and in the downlink, is time diversity, with time delays of few minutes to combat deep fades (Ismail and Watson 2000). By transmitting the same data at least twice, with a delay of a few minutes (this delay is a function of rain attenuation; see Matriciani 2006), the receiver could recover the original data by replacing the portion corrupted by many errors with a version much less corrupted. This method, of course, can be applied only to non-real-time data communication and requires more capacity because at least two identical digital streams must be transmitted. In conclusion, it seems hard to devise real-time diversity countermeasures to rain attenuation for land-mobile channels and real-time communications.

PROPAGATION CHARACTERISTICS OF THE LAND-MOBILE SATELLITE CHANNEL

Several impairments affect the propagation of electromagnetic waves in a land-mobile satellite channel. With regard to terrestrial mobile communications, multipath and shadowing affect the received signal at any frequency band (the so-called “clear-sky” conditions); however, at frequencies above approximately 10 GHz, tropospheric effects also become very important. At these higher frequencies, the attenuation of the electromagnetic wave is due to hydrometeors (rain, snow, ice crystals, clouds) and atmospheric gases (oxygen, water vapor), and strongly depends on frequency, elevation angle, locality, and

weather conditions (Crane 2003). In any mobile communication system it is fundamental to understand and model the characteristics of the electromagnetic wave propagation because link margins must be specified according to the type of environment and weather conditions.

Clear-Sky Channel

A clear-sky channel refers to a channel in which the propagation of electromagnetic wave is not affected by rain or heavy clouds. In this case, the received signal can be modeled as the sum of the direct and ground-reflected waves (coherent components) and the diffuse wave (incoherent component) because rays propagate as light (ray optics; Jakes 1994).

The *direct component* is received through a line-of-sight path. It is subject to free-space attenuation when the first Fresnel ellipsoid is cleared (Friis transmission formula applies; see Friis 1946), to attenuation due to shadowing, and to scintillation and depolarization caused by a turbulent troposphere or the ionosphere.

The main effects of the ionosphere are *depolarization* (or Faraday effect) and *scintillation* (Richharia 1999). Depolarization of linear polarized electromagnetic waves occurs because the ionosphere is birefringent in the presence of Earth’s magnetic field; it is usually predictable (except under unusual atmospheric conditions such as a magnetic storm) and can be compensated by adjusting the polarization of the receive antenna. Its impairments can be minimized by using circular polarization at those frequencies (less than approximately 10 GHz) for which the effect can be significant.

Rapid fluctuation of signal amplitude, phase, polarization, or angle of arrival is known as *scintillation*. Ionospheric scintillation occurs because of small-scale variations of the ionosphere refractive index and is mainly experienced below ~4 GHz; however, in extreme conditions (e.g., during a magnetic storm or near the equator), scintillation can degrade a signal up to 7 GHz. Near the geomagnetic equator (the imaginary great circle on the Earth’s surface formed by the intersection of a plane passing through the Earth’s center perpendicular to the axis connecting the north and south magnetic poles), ionospheric scintillation is typically the most severe impairment experienced by land-mobile satellite systems at L, S, and C bands.

Shadowing is the attenuation of the direct component caused by any type of obstacle: trees, buildings, hills, or mountains. Measurements have shown that shadowing causes the main distortion of the received signal and determines the power margins necessary to provide a tolerable link budget to the user. The intensity and statistical frequency of shadowing depends on the elevation angle, the carrier frequency, the type of obstacle, the path length through the obstacle, and the direction of vehicle travel with respect to the satellite.

The *specular component* reflects from the ground. The reflected power depends on the roughness of the terrain and is larger for a terrain that, at a given wavelength, appears smooth (i.e., the standard deviation of the terrain roughness is small compared to the electromagnetic wavelength; Beckmann and Spizzichino 1987). As a consequence, the reflected power can largely vary in urban,

suburban, and rural environments at high microwave frequencies. This component, however, usually reaches the receiver at a large angle relative the direct path, so that its contribution to the overall received signal in the satellite link can be ignored when a directive (high-gain) antenna is used. It is usually neglected in modeling the land-mobile satellite channel.

The *diffuse component* is due to multipath caused by the reflections and scattering from the space around the receiver, more specifically from outside the first Fresnel ellipsoid (which determines the line-of-sight path). This component is responsible for the small-scale variations of the signal amplitude and phase. Its power depends, at any time, on the distribution of the scattering objects surrounding the receiver. Scintillation due to the troposphere is described in the following section.

If directive antennas and carrier frequencies at L and S bands are used, then shadowing and multipath are the phenomena that dominate the land-mobile satellite channel because tropospheric effects are still negligible. This is why most studies consider only these two phenomena without even mentioning tropospheric effects.

Tropospheric Channel

Besides the clear-sky phenomena mentioned previously, at frequencies $f > 10$ GHz tropospheric phenomena cannot be ignored whenever high channel availability is required. If shadowing, obstruction, and multipath are avoided or taken care of, tropospheric phenomena remain the irreducible cause of fading and system outage, and determine the link budget (Ippolito 1989).

The main atmospheric factors affecting the propagation of electromagnetic waves in fixed or mobile satellite communication systems are due to the lower part of the atmosphere in which meteorological phenomena develop, the troposphere:

1. Attenuation (absorption) caused by atmospheric gases
2. Attenuation (scattering and absorption) and depolarization (a fraction of energy from the incident polarization is coupled to the orthogonal polarization) caused by hydrometeors (mainly rain but also hail, wet snow, ice, clouds, and fog)
3. Scintillation due to the rapid variations of amplitude and phase caused by refractive index irregularities (turbulence)

Any time there is energy absorption, there is also an increase of the system noise temperature, so that tropospheric phenomena affect the carrier-to-noise ratio in two ways: the carrier power is reduced (attenuation) and the noise power is increased, but the latter phenomenon must be considered only if the antenna is directive. Otherwise, the noise temperature entering the antenna is maximized at about 293 K.

Many gaseous constituents of the atmosphere can interact with electromagnetic waves. However, at frequencies up to approximately 300 GHz, only *oxygen* and *water vapor* produce significant absorption. The first three absorption bands are centered at about 22.2 GHz (H_2O), 50–70 GHz (O_2), and 119 GHz (O_2 ; Ippolito 1986). The attenuation is

due to the permanent magnetic moment of the oxygen molecule that interacts with the magnetic field of the electromagnetic wave, and to the electric dipole of water vapor molecule that interacts with the electric field of the electromagnetic wave. These interactions cause a change in the rotational energy of the molecules that absorb in this way energy from the electromagnetic wave. The attenuation due to water vapor exhibits noticeable daily, seasonal, and geographical variations. In the absorption bands, satellite communication is either very demanding or impossible (Matricciani and Riva 1998a).

Hydrometeor is the general term that refers to the products of condensed water vapor in the atmosphere and observed as rain, hail, snow, ice, fog, and clouds. The presence of hydrometeors in the radiowave path, particularly rain, can produce major impairments to space communications that rapidly increase with frequency. Raindrops both absorb and scatter electromagnetic wave energy. They also depolarize the wave, thus reducing the benefits of frequency reuse, and induce rapid amplitude and phase fluctuations, antenna gain degradation, and bandwidth coherence reduction. However, even for the relatively large bandwidths needed for multimedia communication, only absorption, scattering, and depolarization are important. Because these latter phenomena are the main causes that reduce the energy of the electromagnetic wave directed to a polarization-matched antenna, their overall effect on the link budget is twofold: fading (i.e., what is termed *rain attenuation*) and the increase of the thermal noise in the receiver. The noise temperature of this additive white Gaussian noise can be approximately calculated by considering rain as a passive two-port circuit at the physical temperature of rain, with the same attenuation. A conservative estimate of this noise temperature is approximately 293 K.

Rain attenuation becomes significant when the wavelength of the electromagnetic wave in water, $\lambda_o/\sqrt{\epsilon_r}$ (λ_o , wavelength in vacuum; $\epsilon_r \approx 80$, relative dielectric constant of water) is comparable to the hydrometeor diameter (Oguchi 1983). Because the largest diameter of a raindrop can be 9–10 mm for high rain intensity (rain rate), it turns out that rain attenuation is significant only for frequencies higher than approximately 9–10 GHz, and that at L, S and C bands can be neglected.

The classical development to determine rain attenuation assumes that the intensity of the electromagnetic wave decays exponentially as it propagates in the rainy path. The raindrops are usually assumed to be ellipsoids (and, as such, they cause depolarization of the electromagnetic wave), and the contribution of each drop is additive and independent of that of other drops. Rainfall, is in fact, built up by many drops of different diameter and shape, synthetically described by a raindrop size distribution.

In contrast to clear-sky effects, rain attenuation, A , is always measured and calculated in decibels. The rain attenuation of an electromagnetic wave propagating in a slant path of rain of extent L km (rainy path length) in the direction of wave propagation can be expressed as:

$$A = \int_0^L Y(x) dx \text{ (dB)} \quad (1)$$

where Y is the specific attenuation (dB/km). For practical applications, the relationship between specific attenuation Y (dB/km) and rain rate R (mm/h) can be expressed as a nonlinear function of a physical quantity, the rain rate R (mm/h), which can be measured on site with a rain gauge, a robust and reliable device. The relationship between R and Y can be approximated by the power law

$$Y(x) = kR^\alpha(x) \text{ (dB/km)} \quad (2)$$

where k and α are assumed to be constants along the path but dependent on frequency, polarization, and temperature. Values of k and α have been calculated for many frequencies (Olsen, Rogers, and Hodge 1978; Maggiori 1981). The values given by Maggiori (1981) are those recommended by the International Telecommunication Union-Radio Communication Sector (ITU-R 1992a).

Hail and snow can also be present in a satellite path and can induce significant fades. Ice can produce significant depolarization with very little attenuation (Cox and Arnold 1984). Wet snow or rainfall, if not quickly removed from an antenna dish, can produce significant attenuation (Crane 2002).

Rain attenuation varies statistically from year to year, from season to season, from hour to hour of the day, being usually larger in summer (huge rain storms) than in winter, and larger in the afternoon and evening hours than in the morning and evening hours, at least for localities with temperate climates (Lin, Bergmann, and Pursley 1980; Goldhirsh 1980; Fukuchi et al. 1981; Cox and Arnold 1982; Matricciani 1998, 2000b, 2004).

Rain attenuation is a slow phenomenon both for fixed and mobile receivers, and is independent of antenna directivity. The average power spectrum of time series of fading during rain rapidly sampled (50 samples/s) in a fixed satellite link shows that significant power due only to rain attenuation can be found up to about 0.01–0.03 Hz.

The spectrum at higher frequencies is dominated by the tropospheric turbulence, whose effects are statistically dependent on the simultaneous rain attenuation (Matricciani, Mauri, and Riva 1996; Matricciani and Riva 2005a).

Figure 1, for instance, shows the experimental average power spectrum obtained from many time series of fade at 18.7 GHz collected during rain in a 37.7 degree slant path to satellite Italsat, with a 3.5 m receiving antenna (Matricciani and Riva 2005a). It shows the typical shape predicted for a turbulent atmosphere with a complex refractive index, with two frequency intervals of different and definite slopes, separated by a frequency interval with a flatter spectrum. Up to frequencies of few hundredths of hertz we can observe the “classical” -20 dB/decade slope due only to rain attenuation (Matricciani 1994). The slope starts to change its magnitude at about $0.02 - 0.03$ Hz. For frequencies larger than about 0.3 Hz, the classical $-80/3$ dB/decade slope due only to scintillation (i.e., $-8/3$ in natural units; Tatarski 1961) clearly appears.

As for frequency scaling, for not too large a range at microwaves, rain attenuation A_2 (dB) at a carrier frequency f_2 can be empirically related to rain attenuation A_1 (dB) exceeded for the same probability at a carrier frequency f_1 , in the same slant path, by the power law:

$$A_2 = A_1(f_2/f_1)^a \quad (3)$$

where a is an empirical parameter ranging from 1.7 (Druifuca 1974) to approximately 2.2 (OPEX 1994).

As for elevation angle scaling, the following formula, derived by assuming a direct proportionality between A and slant rainy path length and valid for $\theta > 5$ degrees approximately, can be used to obtain a first approximation:

$$A(\theta) = A(\theta_o) \sin \theta_o / \sin \theta \quad \text{(dB)} \quad (4)$$

Figure 1: Average power spectrum of fade time series at 18.7 GHz during rain (using a 3.5 m diameter antenna, with sampling rate 50 Hz, up to the Nyquist frequency 25 Hz)

Note: Notice the -20 dB/dec slope due to rain (rain absorption and scattering) and the $-80/3$ dB/dec slope due to troposphere turbulence (scintillation). Receiver noise, given by the flat portion above approximately 3 Hz, limits the range of the measurements. The “spikes” observed are due to the satellite, but they can be neglected because most of their power can be filtered out together with the receiver noise above 3 Hz.

where θ and $A(\theta)$ are, respectively, the new elevation angle and rain attenuation, and θ_0 and $A(\theta_0)$ are the reference values.

Depolarization in precipitation is caused by the differential attenuation and phase shifts induced between orthogonal components of an electromagnetic wave by anisotropic hydrometeors (Chu 1971; DiFonzo, Tracchtman, and Williams 1976; Cox 1981; Capsoni et al. 1981; Allnutt 1989; Cox and Arnold 1984). For a frequency-reuse system the importance of depolarization depends on frequency, path geometry (elevation angle and tilt angle of the received polarization) and climatological factors (severity of the rainfall), and sensitivity to the interference coming from the cross-polarized signal. In systems that are operating with one polarization only, depolarization causes a small apparent increase in the path attenuation.

Although rain is the most significant constituent affecting electromagnetic wave propagation, *clouds* (Dissanayake, Allnut, and Haidara 1997) and *fog* can also be present in a satellite path and attenuate the signal. The attenuation due to suspended water droplets contained in clouds can be determined with great accuracy up to approximately 100 GHz, using the Rayleigh model of electromagnetic wave scattering. This physical approach requires the assessment of the cloud vertical profile, information that can be derived from radiosonde measurements (Vasseur and Vanhoenacker 1998). Clouds attenuation is proportional to the liquid water content rather than to the drop size distribution, as in the case of rain attenuation, and is highly variable. Cloud and fog attenuation can become significant at millimeter waves (>30 GHz).

Short-term fluctuations in radiowave amplitude and phase, referred to as *scintillation* (as for the visible optical frequencies) are generated by small-scale refractive index inhomogeneities. Tropospheric scintillations are faster than rain attenuation, with a distinct spectrum appearing at frequencies above approximately 0.1 Hz (Figure 1). Both fades and enhancements around the average signal level are observed (multiplicative effect in natural units, additive in decibels) that can be interpreted as alternate destructive and constructive interference among multiple rays. Since scintillation is not caused by an energy-loss mechanism, turbulence does not increase the system noise.

Tropospheric scintillation is usually significant only at low elevation angles or with antennas of small size, although noticeable cloud scintillations occur at much higher elevation angles. There is a distinct seasonal dependence, with frequency of occurrence approaching a maximum in summer and a minimum in winter. The magnitude of tropospheric scintillation increases moderately with frequency because its standard deviation, in decibels, increases as $f^{1/2}$. The intensity of scintillation increases with path length through the turbulent medium and decreases as the antenna beam width decreases, because of antenna aperture averaging (Tatarski 1961). Measurements at two different polarizations show that scintillation is independent of polarization (Cox 1981; Matricciani and Riva 1998b).

Scintillations are unlikely to produce serious fading in space communication systems below approximately 10 GHz and in slant paths of elevation angles above

10 degrees. Below 10 degrees and above 10 GHz, tropospheric scintillation can be a source of significant outages in satellite systems with very low power margins. Scintillation is found also during rain attenuation, to which it is correlated (Matricciani, Mauri, and Riva 1996; Matricciani and Riva 2005a), and may produce short outages (~ 1 s).

FREQUENCY AND TIME SELECTIVITY

Regardless of satellite type of orbit, the motion of the receiver induces time-varying channel characteristics. When the environment changes significantly (e.g., moving from urban to suburban or rural areas), clear-sky fading becomes nonstationary and more difficult to model. A simple way to model this phenomenon was introduced by Bello (1963), who proposed the notion of a wide-sense stationary channel with uncorrelated scattering, with a single state or multiple states. A single-state model describes the propagation channel only with a single, spatially invariant, statistical distribution. A multistate model describes the propagation channel with a collection of single-state models and accounts for macro-variations of the channel through probabilistic state transitions.

Large-scale fading and large-power variations are experienced when the mobile terminal travels several hundred wavelengths. Small-scale fading and possibly large-power variations are experienced when the mobile terminal travels few wavelengths because the signal amplitude changes due to constructive and destructive interference in the sum of multiple rays (multipath), mainly caused by reflections from the surrounding surfaces. In this case, power fluctuations are measurable over distances comparable to the wavelength, as small as a half wavelength.

The Fourier transform of the transfer function of the channel is modeled according to a wide-sense stationary uncorrelated random process both in frequency f and time t (Bello 1963; Durgin 2003; Parsons 2000). From the transfer function, the first- and second-order fading statistics can be estimated. First-order statistics provide the probability density function (Pdf) and the cumulative density function (Cdf, the integral of Pdf) of the received signal envelope and phase for each distinct path. Second-order statistics provide the autocorrelation properties of the fading both in the time domain (Doppler spectrum, level crossing rate and fade duration) and in the frequency domain (multipath intensity profile, delay spread; Jakes 1994).

In detail, considering a couple of frequencies (f_1, f_2) and times (t_1, t_2), the autocorrelation function $\Re(f_1, f_2; t_1, t_2)$ satisfies the condition

$$\Re(f_1, f_2; t_1, t_2) = \Re(\Delta f; \Delta t) \quad (5)$$

with $\Delta f = f_2 - f_1$ and $\Delta t = t_2 - t_1$.

The radiofrequency bandwidth that produces the function $\Re(B_c) \equiv \Re(B_c; 0)$ is known as the channel *coherence bandwidth* B_c and measures the channel memory in the frequency domain. In this bandwidth all spectral components of the transmitted signal pass through the

channel with equal gain and linear phase (i.e., the channel remains invariant).

Similarly, the time interval that produces the function $\Re(T_c) \equiv \Re(0; T_c)$ is known as the channel *coherence time* T_c , which measures the channel memory in the time domain. This is the time interval during which the channel impulse response remains invariant.

These two memory indicators are inversely related to a pair of fundamental parameters. The coherence bandwidth B_c is related to the time delay spread T_s , according to:

$$T_s \approx \frac{1}{B_c} \quad (6)$$

The coherence time T_c is related to the Doppler frequency spread B_d (due to multipath) according to:

$$B_d \approx \frac{1}{T_c} \quad (7)$$

A useful concept is the selectivity in time and frequency. Let $R_s = 1/T$ (symbols/s) be the symbol rate of the transmitted signal. Then the fading is not selective in frequency; in other words, it is “flat” if $T \gg T_s$ (i.e., the delay spread produces negligible time dispersion on the signal). However, flat-fade channels may cause deep fades. Assuming that the signal radiofrequency bandwidth B_{RF} is the order of $1/T$ (i.e., $B_{RF} \approx 1/T$), nonselectivity in frequency means $B_{RF} \ll B_c$. In this case, the channel is termed *narrowband*. On the other hand, if $B_{RF} \gg B_c$, the channel has a constant gain and linear phase response only in a bandwidth much smaller than the radiofrequency bandwidth, and *frequency-selective* fading is experienced.

For instance, a QPSK modulation scheme delivering a total data rate R_b (bit/s) would need a radiofrequency bandwidth $B_{RF} = (1 + \delta)R_b/2$ (in this case, considering the equivalent baseband channel, the symbol rate and the bit rate coincide $R_b = R_s$), with $0 < \delta \leq 1$ being the roll-off factor of the raised cosine pulses sent to the receiver sampler.

In conclusion, the fading is flat when the signal bandwidth is much less than the coherence bandwidth,

$B_{RF} \ll B_c$ (*narrowband* channel). In this case, fading is also multiplicative; in other words, it is additive in decibels, or all frequency components undergo the same attenuation and phase shift. The fading is selective in frequency and introduces significant time dispersion and frequency distortion if $B_{RF} \gg B_c$ (*wideband* channel).

Depending on frequency flatness or selectivity, statistical models are classified as narrowband or wideband, respectively. Most land-mobile satellite models are narrowband, because they have been devised for the actual data rate and satellite environments in which the direct component is generally strong, and multipath power is relatively low and can be neglected.

Fading is nonselective in time if $T \ll T_c$ (i.e., if the symbol period T is significantly smaller than the coherence time T_c). This means that the Doppler spread B_d is much smaller than the radiofrequency bandwidth, $B_d \ll B_{RF}$. The channel is then affected by *slow fading* because the channel impulse response changes slowly within the symbol duration. If this condition is not verified, the fading is selective in time, and deep fading can be experienced at particular times because of destructive interference. The channel is then affected by *fast fading* because the channel impulse response changes rapidly within the symbol duration. Tables 1 and 2 summarize the various cases just discussed.

In addition to the multipath Doppler spectrum, in land-mobile satellite communications there is an additional frequency shift—the conventional Doppler offset due to the satellite relative motion—that is very important when satellites are not in the geostationary orbit (MEO and especially LEO systems).

The mobile terminal moves in an environment whose space characteristics can be described by a coherence distance for small- and large-scale fading events. The *shadowing* (or *large-scale*) *coherence distance* is the distance that the receiver must travel to experience uncorrelated (zero correlation coefficient) large-scale fading events. The *small-scale coherence distance* is the distance that the receiver must travel to experience uncorrelated small-scale fading events. Obviously, the shadowing coherence distance is much larger than the small-scale coherence distance. Given a specific receiver speed, this means that small-scale fading events are much faster (a larger number

Table 1: Types of Fading Dependent on Time Delay Spread T_s and Its Characteristics

Characteristic of the Channel	Frequency-Flat Fading	Frequency-Selective Fading
Symbol period of the signal, T	Greater than channel delay spread, $T \gg T_s$	Smaller than channel time delay spread, $T \ll T_s$
Coherence bandwidth of the channel, B_c	Greater than the radiofrequency bandwidth (narrowband channels), $B_c \gg B_{RF}$	Smaller than the radiofrequency bandwidth (wideband channels), $B_c \ll B_{RF}$
Type of fade	Deep fade requiring more transmitter power to achieve the tolerable probability of bit error	Selective fade causing intersymbol interference; more transmitter power will not reduce it
Modeling difficulty	Relatively easier than modeling frequency-selective fading	Relatively more difficult than modeling frequency-flat fading

Table 2: Types of Fading Dependent on Doppler Frequency Spread B_d and Its Characteristics

Characteristic of the Channel	Slow Fading	Fast Fading
Coherence time of the channel, T_c	Greater than the symbol period of the signal, $T_c \gg T$; the channel is static over one or several symbol periods	Smaller than the symbol period of the signal (time-selective fading), $T_c \ll T$
Doppler frequency spread of the channel, B_d	Smaller than the radiofrequency bandwidth, $B_d \ll B_{RF}$	Greater than the radiofrequency bandwidth, $B_d \gg B_{RF}$
Type of fade	Channel changes slower than the baseband signal variations	Channel changes faster than the baseband signal variations In <i>fast flat-fading channels</i> , the amplitude of the received signal changes faster than the rate of change of the baseband signal In <i>fast frequency-selective fading channels</i> , the amplitude, phases and time delays of the multipath components change faster than the rate of change of the baseband signal
Modeling difficulty	Relatively easier than modeling fast fading	Relatively more difficult than modeling slow fading

of very short fades per unit of time) than large-scale fading events.

With regard to time, frequency, and space correlation, the *angular coherence* is the angle separation needed to experience uncorrelated fading events. The angular coherence measures the channel memory in the angular domain. Again, a distinction between small- and large-scale fading can be useful. The angular coherence is useful in the design of antenna arrays and beam-forming networks, and for angle diversity analysis.

With regard to rain attenuation, since absorption and scattering are not frequency selective up to approximately 100 GHz, even for bandwidths of a few hundred megahertz, a channel affected only by rain attenuation is flat in frequency; in other words, it is always $B_{RF} \ll B_c$, or the channel is always narrowband. With regard to selectivity in time, deep fades are measured when intense rainfall cells are along the satellite slant path. Deep fades may last a few minutes and are statistically described by fade duration statistics. Rain attenuation coherence distance is of the order of several hundreds of meters; hints can be obtained perhaps by considering a satellite site-diversity gain with station separation of 500–750 m (Matricciani 2003). With regard to the angular coherence of rain attenuation, hints can be derived via an angle- (orbital-) diversity gain at K_u band (Matricciani 1987).

CLEAR-SKY MODELING

The purpose of channel modeling is to understand the propagation phenomena that dominate the land-mobile satellite channel and to derive rules and expressions that can describe, statistically, the dependence of the received signal as a function of frequency, elevation angle, antenna type, and directivity (antenna gain); relative velocity between receiver and satellite; locality; type of environment (urban, suburban, rural); and weather conditions (clear sky, rain, etc.).

Accurate propagation modeling is fundamental to calculate link budgets and perform realistic quality-of-service predictions. A large number of proposed models exists for both clear-sky and rainy conditions, most of which have been obtained by a best fit to the available experimental data. Therefore, the selection of a particular model should be tightly linked to its use in performance predictions.

Extensive measurements, at UHF and especially at L and S bands, conducted in clear-sky conditions all over the world (e.g., see Goldhirsh and Vogel 1998) have provided data useful to model the land-mobile satellite channel and have produced several models, mainly empirical, for narrowband channels. Multimedia services, however, may require larger bandwidths, if they must compete and coordinate with the fixed and mobile terrestrial communication networks, so that wideband modeling is also necessary.

Narrowband Models

The narrowband models can be classified as empirical, statistical, or analytical (Karaliopoulos and Pavlidou 1999). The empirical and statistical models are the most developed and tested, whereas the analytical models are mainly concerned with the terrestrial mobile channel (as a result, we will not cover them here).

Empirical Models

Empirical models provide a mathematical function obtained by a best fit (regression) on the measured data, and, as such, they may not provide insight to understand the physical phenomena that cause attenuation. Their main advantage is the simplicity of the final mathematical expressions and easy application, but their disadvantage is that they are related to data measured at a particular site and may not be reliably applicable to other sites.

These models predict either the average attenuation caused by vegetation (mainly trees) or the link margin needed to compensate for propagation line-of-sight loss and other fades. The modeling concerns various parameters such as elevation angle, carrier frequency, path length through the vegetation, and other parameters related to the specific environment in which the measurements were made (Goldhirsh and Vogel 1998). These parameters are nearly always computed by a best fit to the measured data. Kanatas and Konstantinou (1996) provide a classification and comparison of the several empirical models proposed.

Statistical Models

Statistical models offer insight into the physical phenomena that affect the propagation of electromagnetic waves, but their application usually requires methods of numerical analysis. These models define first-order statistics (i.e., the probability density function and the cumulative probability density function of the envelope, and sometimes of the phase, of the received signal). The knowledge of these statistics is fundamental to predict adequate fade margins. Fewer studies have considered the modeling of second-order statistics, such as statistics of fade duration and level crossing rate, useful for selecting modulation and coding techniques.

There are two modeling approaches to derive *first-order* statistics: global and state-oriented. The *global* approach models the shadowing and multipath phenomena with a single probability distribution. The *state-oriented* approach models the shadowing and multipath phenomena in more detail, because it describes with a single distribution each of the several discrete states that the channel can have.

The usual, although not precise, classification of environments for global channel modeling is *urban*, *suburban*, or *rural*. There seems to be no distinction for the different architectural styles and street dimensions of the cities of the world, although, for instance, European cities are quite different from North American cities. A rural environment implies the existence of a line-of-sight path, in which a significant part of the electromagnetic wave reaches the receiver without being reflected or scattered. An urban environment, on the other hand, usually excludes the existence of a line-of-sight path, and the receiver is surrounded by a large number of scattering objects. Therefore, multipath is the main propagation mechanism. The suburban environment is intermediate and combines the characteristics of both urban and rural environments.

Let the baseband equivalent received signal sample in the presence of nonselective fading be defined as:

$$y = gx + n \quad (8)$$

where x is the complex transmitted signal, g is the multiplicative complex fading channel coefficient, and n is a complex additive white Gaussian noise with zero average and one-sided power spectral density N_o . In particular

$$g = re^{j\theta} \quad (9)$$

where r is the fading envelope and θ is the phase rotation introduced by the channel. The average power associated with the fading envelope is given by $E[r^2] = P$, usually normalized to unity, a value that represents the average power that would equal received propagation in free-space conditions.

Variations of the signal amplitude, r , due to attenuation caused by any type of obstacle impeding the line-of-sight path (large-scale fading) is well modeled by the log-normal distribution (Cox, Murray, and Norris 1984). The distribution used to model the variations of signal amplitude due to multipath (small-scale fading) depends on the scattering environment and on the assumption made about the components of the received wave. In urban environments, multipath is well described by a Rayleigh distribution. Now, the Rayleigh Pdf implies that an infinite number of scattering elements contribute to the resultant electromagnetic wave amplitude and phase, but this is a sufficient and not necessary condition, so that it is also experimentally found when a finite number of rays contribute to the received signal. In rural and suburban environments, in which a line-of-sight component exists for most of the time, Raleigh fading turns into Ricean fading (Lee 1995; Pattan 1998).

Large-scale shadowing can be described by a Gaussian distribution in decibels that in linear scale turns into the *log-normal distribution*, given by

$$f(r) = \frac{1}{\sqrt{2\pi}r\delta} \exp\left[-\frac{(\ln r - \mu)^2}{2\delta^2}\right] \quad (10)$$

where δ (neper) is the standard deviation and μ (neper) is the average of the normal (i.e., Gaussian) random variable $\ln r$.

The *Raleigh distribution* (applicable to urban areas) is derived by assuming that no direct component is present (i.e., that none of the multipath components prevails) and by applying the central limit theorem to the two orthogonal components of the received envelope r , which thus result in Gaussian random variables with zero average and standard deviation σ (Sklar 1997a, 1997b). The channel coefficient g becomes a zero-mean complex Gaussian variable with uniform phase distribution in $[0, 2\pi]$, and the envelope r is distributed according to the Rayleigh Pdf, given by

$$f(r) = \frac{r}{\sigma^2} \exp\left[-\frac{r^2}{2\sigma^2}\right] \quad (11)$$

where $2\sigma^2 = P$.

There is a direct component in rural and suburban environments, and fading can be modeled according to the *Rice distribution* (Lee 1995). This Pdf assumes a constant power for both direct and diffuse components and is given by

$$f(r) = \frac{r}{\sigma^2} \exp\left[-\frac{r^2 + s^2}{2\sigma^2}\right] I_0\left(\frac{rs}{\sigma^2}\right) \quad (12)$$

where σ^2 has the same meaning as for the Rayleigh distribution, s is the magnitude of the direct component, and $I_0(\cdot)$ is the zero-order modified Bessel function of the first kind. Now $P = s^2 + 2\sigma^2$.

To jointly describe large- and small-scale fading, a composite Pdf is used. The *Suzuki distribution* (Suzuki 1977) combines Rayleigh and log-normal statistics as follows:

$$f_r(r) = \frac{r}{\sqrt{2\pi}\delta} \int_0^\infty \frac{1}{\sigma^3} \exp\left[-\frac{r^2}{2\sigma^2} - \frac{(\ln \sigma - \mu)^2}{2\delta^2}\right] d\sigma \quad (13)$$

where $2\sigma^2$ is the average received power for the Rayleigh process, and δ and μ , respectively, are the standard deviation and the average value of the log-normal distribution.

The *state-oriented* approach models the long-term variations of the channel and its transitions to different states as a Markov process. A Markov process is a stochastic process that can model a system that exists only in discrete states. Short-term variations, corresponding to each individual discrete state, are described by one of the Pdfs mentioned earlier, with appropriate parameters. The probability of being in one of these states depends only on a finite number of previous states (one, two, etc.). Two matrices must be computed to define the process completely: (a) the $1 \times M$ state probability array \mathbf{S} whose elements, S_i , express the probability of the system being in state $i = 1, 2, \dots, M$; (b) the $M \times M$ transition probability matrix \mathbf{P} , whose elements P_{ij} give the probability of transition from state i to state j . Models considering one, two (Lutz et al. 1991), or three states (Karasawa, Kimura, and Minamisono 1997; Perez-Fontan et al. 1997a, 1997b) have been fitted to experimental data. In this case, state 1 describes the line-of-site condition, state 2 the moderate fading conditions, and state 3 the deep fading conditions.

The *second-order* statistics are the level crossing rate and the average fade duration (Lee 1995; Loo 1985; Hasey, Goldhirsh, and Vogel 1991). They are useful channel parameters to design interleaver and forward-error correcting codes for mitigating fading effects.

The level crossing rate, N_R , at a specific level $r = R$, is the expected rate at which the envelope crosses that level in a positive-going direction, and is given by

$$N_R = \int r' f(R, r') dr' \quad (14)$$

where “'” indicates a time derivative and $f(R, r')$ is the joint probability density function of the envelope r and its derivative r' at $r = R$.

The average fade duration under a specified level $r = R$ is the average duration of the intervals during which the envelope falls below that level. If τ_i is the duration of the i -th fade interval, the probability that $r \leq R$ during a time interval T can be written as

$$P(r \leq R) = \frac{1}{T} \sum_i \tau_i \quad (15)$$

and the average fade duration, $\bar{\tau}$, is given by

$$\bar{\tau} = \frac{1}{TN_R} \sum_i \tau_i = \frac{1}{N_R} P(r \leq R) \quad (16)$$

Sometimes these data are obtained by a best fit on directly measured time series of fading.

Wideband Models

For both terrestrial and mobile satellite channels, wideband effects are mainly modeled by considering the impulse response of the channel in the presence of a finite number of scatterers surrounding the receiver. Geometrical (ray) optics applies. As a consequence, the time-varying impulse response, $h(t, \tau)$, of the channel is written as (Rappaport 2001):

$$h(t, \tau) = \sum_{i=0}^{N-1} A_i(t) \delta(t - \tau_i(t)) e^{j\theta_i(t)} \quad (17)$$

where $A_i(t)$, $\tau_i(t)$, and $\theta_i(t)$ are the random time-varying amplitude, arrival time, and phase sequences, respectively; δ is the delta function; and $N - 1$ is the number of scattered wave components considered. The term for $i = 0$ represents the direct component, if there is one, and the other $N - 1$ terms represent the echoes due to multipath.

The expression for the channel impulse response suggests that it can be modeled by a tapped delay line (Rappaport 2001). This approach has been widely accepted and employed by most investigators of the terrestrial mobile channel. The several models proposed aim at defining suitable distributions for the amplitudes $A_i(t)$ (the tap gains), the delay times $\tau_i(t)$, and the Doppler spectrum of each tap or the time correlation of each discrete path (tap) gain. The same approach is followed in the few studies dedicated to the land-mobile satellite channel. The choice of the relative distributions for each model and the number of path taps is based on statistical analysis of measurements.

TROPOSPHERIC CHANNEL MODELING AT HIGH FREQUENCIES (>10 GHz)

At frequencies between 10 and 300 GHz, electromagnetic waves can be faded because of the presence of hydrometeors (rain, snow, ice crystals, clouds) in the lower part of the atmosphere, the troposphere, and atmospheric gases (oxygen, water vapor). The characteristics of this fade strongly depend on frequency, elevation angle, locality, and climatological conditions. In the following we consider only rain attenuation because at K_u band (12–14 GHz) and K_a band (20–30 GHz), the bands to be used next for multimedia communications with fixed and mobile terminals, rain is the most important physical phenomenon to be considered (Matricciani and Riva 1998a).

There are no real measurements of rain attenuation experienced by a moving terminal—only reliable simulations (Matricciani 1995, 2000a; Matricciani and Moretti 1998; Matricciani and Selva 2002). Both first-order and

second-order long-term statistics of rain attenuation likely to be experienced by a moving terminal can be, however, estimated from knowing:

1. Rain attenuation statistics experienced by fixed-system terminals
2. Type of motion of vehicles

In the following sections, we first discuss rain attenuation statistics experienced in fixed systems (which directly apply to gateway stations) and then extend them to mobile receivers.

Rain Attenuation Statistics for Fixed-System Satellite Communications

Contrary to the statistical models developed for clear-sky conditions, most statistical models of rain attenuation are empirical, and, as such, they seldom offer physical insight into the complex phenomena that cause rain. Physical models, on the contrary, are based more on the physical-mathematical relationship between rain rate along the slant path and rain attenuation. The most reliable and accurate physical model is the synthetic storm technique (SST), discussed in more detail later in the chapter.

Statistical Models

Rain attenuation can be assessed accurately by measuring, in a very narrow bandwidth close to the communication signal bandwidth, the received power of an unmodulated sinusoidal carrier (a satellite beacon). Propagation experiments, however, are very expensive and lengthy, if they are to be statistically reliable, so that they are carried out only in a few places in the world and for a limited number of years, frequencies, and link geometry. As a consequence, their results cannot be easily and directly applied to any site in the world. For this reason, many statistical models of the long-term complementary probability distribution function (cPdf) of rain attenuation (this is the cumulative probability that a given rain attenuation A [dB] is exceeded in a slant path) have been developed in the last three decades (Riva 2002) to predict this *first-order* statistic. Because rain attenuation is not frequency selective, even for bandwidths of tens of megahertz, there is no need to distinguish between narrowband and wideband models.

For a slant path to a satellite, all statistical models give the long-term rain attenuation cPdf using as physical input the rain rate cPdf measured on site or estimated from climatological global statistical maps of rain rate, and of the rain height, often approximated by the altitude of the 0 degree Celsius isotherm above mean sea level. Most models, however, have derived their parameters by a best fit on the experimental data available at the time of their development, and, as such, they do not provide a significant physical insight. Very few models have based their theory and modeling on some approximate physical features that describe, on the average, the complex meteorological phenomena (e.g., radar measurements or arrays of rain gauges). When these statistical models (approximately fifteen) are tested against concurrent satellite beacon measurements, they show, however, very similar large errors (Riva 2002). Although the ITU-R (2003a)

recommends a particular prediction method—see Riva (2002)—a reliable assessment of the predicting power of most models seems hard because the data bank used to test them may be inaccurate and far from controlled “laboratory” conditions necessary for any reliable test (Matricciani and Riva 2005b).

Models of *second-order* statistics of fade (fade durations and rate of change of fade) during rain are in a similar stage of development but with worse accuracy. These statistics are useful and necessary because they directly influence some aspects of satellite system design and fade countermeasures—such as the use of common shared resources onboard the satellite, uplink power control, adaptive coding, frequency, and space and time diversity—and determine channel availability statistics.

The statistical models of duration and rate of change of rain attenuation are largely empirical because they rely on a best fit on experimental distributions conditioned to a given rain attenuation. Fade durations measured during rain can vary from a few seconds to hours, a range of about five orders of magnitude, and across this range they are not caused by the same phenomena; however, short fades (~ 1 s) are likely due to scintillation caused by atmosphere turbulence, whereas long fades are caused by the space-time structure of rain (rain attenuation; Matricciani 1981a, 1982a; Matricciani, Mauri, and Paraboni 1987). Therefore, it is difficult to describe the whole distribution using a single mathematical function. In general, the distribution of long fade durations (> 1 min) is modeled by a log-normal Pdf, and the distribution of short fade durations (≤ 1 min) is modeled by a power law or another log-normal Pdf (Paraboni and Riva 1994; ITU-R 2003b).

The rate of change of rain attenuation is estimated after removing most of the signal fluctuations arising from tropospheric scintillations (Figure 1). Positive and negative rates of change (expressed in dB/s) are similar, and their absolute values can be statistically modeled by just one single log-normal Pdf (Lin, Bergmann, and Pursley 1980; Matricciani 1981b, 1982b; Dissanayake et al. 1990; Poiares-Baptista and Davies 1994). They are correlated with the attenuation itself and increase with it. They also depend on receiver filter bandwidth and time lag (period of time over which fade slope is calculated; ITU-R 2003b).

Physical Models: The Synthetic Storm Technique

A physical model based not on a best fit on radio electrical data but on independent meteorological data, such as the rain rate measured by a rain gauge, is the synthetic storm technique. The method of employing rain gauge records to generate attenuation statistics is based on the concept originally used by Hamilton and Marshall (1961) to calculate the effects of rain attenuation on data obtained by a weather radar, according to the “frozen flow” hypothesis (Taylor 1938). Drufuca (1973, 1974) applied the concept to terrestrial microwave links, Matricciani (1994, 1996) to satellite links.

As a rain pattern moves over a rain gauge, the measured rain rate $R(t)$, measured in mm/h, varies with time because of two effects: the horizontal motion (advection) of the spatial pattern of rain and the changes that occur

within the time required to pass over the rain gauge. These two effects are both present in rain gauge records and are not easily separated. A “synthetic storm” is obtained by converting a rain rate time series recorded at a rain gauge to a rain rate space series by using an estimate of the storm translation speed to transform time to distance (this transformation is Taylor’s “frozen flow” hypothesis applied to rain rate). Of course, this description assumes that only advection is present, and it will not give an exact description of the distribution of rain rate with distance. It is true, however, that the statistical properties of rain rate of a large number of synthetic storms are approximately the same as those of real storms. Evidence of the validity of this hypothesis can be found in the special case of convective storms in Montreal up to time lags of 40 minutes (Zawadzki 1973). As the measured average storm speed was about 50 km/h, 40 minutes correspond to a space lag of about 30 km, a length larger than that of most slant paths in Earth-satellite links or horizontal paths (terrestrial links). Zawadzki (1973) showed that there is also a marked isotropy in the patterns, indicating that statistics obtained along the direction of motion of the storm can be extended to the entire precipitation pattern, though the SST is directly applicable to storms with a major component of velocity parallel to the radio path. For widespread rain, the hypothesis of isotropy should hold even more because of the great uniformity in time and in space of this type of rain (Drufuca and Zawadzki 1975). As a consequence of this supposed statistical isotropy, there is no distinction between the direction of the storm motion and the direction of the radio path.

After Matricciani (1996) formulated the theoretical physical-mathematical foundations, established useful theorems, and devised an effective vertical profile of the precipitation that takes the melting layer into account (1991), the SST was developed to a mature stage of insight, understanding, and reliability so that it is now a powerful and accurate tool for predicting rain effects at frequency greater than 10 GHz. It can predict reliable first-order (cPdf of A ; Matricciani 1996; Matricciani and Riva 2005b) and second-order (fade duration and rate of change) statistics (Matricciani 1997, 1998, 2000b, 2004) of rain attenuation that characterizes a slant path for fixed and land-mobile satellite systems (Matricciani and Moretti 1998), because it provides direct rain attenuation time series that could very likely be measured, at any frequency and polarization, for any slant path above approximately 10 degrees. The SST can be used at tropical sites as well (Emiliani, Castanet, and Feral 2005).

The predictions are significantly insensitive to the value of v , and the simulations can use the average value of v , a random variable that can be accurately described by a log-normal probability density function (Binaghi and Pawlina Bonati 1992), independent of site (Matricciani 1996; Matricciani and Moretti 1998). Statistics of v can be obtained from meteorological services. In practice, the average value of v can range from 4–5 m/s to 13–14 m/s.

The vertical structure of rain is modeled using two layers of precipitation of different depths. Starting from the ground, there is rain (hydrometeors in the form of raindrops, water temperature of 20 degrees Celsius, layer A) followed by a melting layer (layer B)—in other words,

melting hydrometeors at 0 degrees Celsius. The rain intensity R (mm/h), with one minute of integration time (i.e., time series with one sample/min), in the lower layer is assumed to be uniform and given by that measured at the ground (i.e., by the rain gauge). Calculations also show that the precipitation rate in the melting layer, termed “apparent rain rate,” can be supposed to be uniform and given by $R_B = 3.134R$ (Matricciani 1991).

For a site in the Northern Hemisphere at latitude ϕ° , the height of the precipitation (rain and melting layer) above sea level is given by ITU-R (1992b) as

$$\begin{aligned} H_B &= 5 & \phi &\leq 23^\circ \\ H_B &= 5 - 0.075(\phi - 23) & \phi &> 23^\circ \end{aligned} \quad (18)$$

For a site in the Southern Hemisphere at (negative) latitude ϕ° , the height of the precipitation (rain and melting layer) above sea level is given by

$$\begin{aligned} H_B &= 5 & \phi &\geq -21^\circ \\ H_B &= 5 + 0.1(\phi + 21) - 71 & -71 &\leq \phi < -21^\circ \end{aligned} \quad (19)$$

ITU-R (2001b) provides a more precise global map of the altitude of the 0 degree Celsius isotherm height above mean sea level.

The height (depth) of the melting layer is $h = 0.4$ km, regardless of the latitude (Matricciani 1991).

Let us first consider a *terrestrial* radio link (parallel to the Earth’s surface) of length L (km) along the horizontal axis x ; let the rain rate R and the specific attenuation Y (dB/km) be linked by equation 2; and assume that k and α (layer A, 20 degrees Celsius) do not change with space or time. Let us consider a reference point x_0 (origin) at the midpoint of L . The attenuation is then given by equation 1, written as

$$A(x_0) = k \int_{x_0-L/2}^{x_0+L/2} R^\alpha(x) dx \quad (20)$$

Now, according to Taylor’s hypothesis applied to rain rate, the variation of attenuation with time can be simulated by changing x_0 at a rate equal to the speed v of the storm motion, that is, at a rate

$$\dot{x}_0 = vt \quad (21)$$

This process can be mathematically described by the convolution between a function of rectangular shape of unit amplitude and width L centered at the origin x_0 , $\text{rect}(x/L)$, and $Y(x)$:

$$\begin{aligned} A(x_0) &= k \int_{-\infty}^{+\infty} R^\alpha(x_0 + x) \text{rect}(x/L) dx \\ &= k \int_{-\infty}^{+\infty} R^\alpha(x) \text{rect}[(x_0 - x)/L] dx \end{aligned} \quad (22)$$

From equation 22 we can obtain the Fourier transform of $A(x_0)$, in the domain of space frequency $f_s = x^{-1}$ km⁻¹, as

$$S_A(f_s) = S_Y(f_s)L \text{sinc}(f_s L) \quad (23)$$

where

$$S_A(f_s) = F[A(x_0)] \quad (24a)$$

and

$$S_Y(f_s) = F[kR^\alpha(x)] \quad (24b)$$

are the Fourier transforms of $A(x_0)$ and $Y(x)$, respectively, and $\text{sinc}(f_s L) = \sin(\pi f_s L)/(\pi f_s L)$. Using linear-systems terminology, we can refer to $S_Y(f_s)$ as the “input spectrum” and to $L \text{sinc}(f_s L)$ as the “path transfer function.”

Now, by converting space to time with equation 21, and noticing that $f(\text{Hz}) = v f_s$, if v is expressed in km/s, the space spectrum $S_A(f_s)$ is transformed into the temporal spectrum $\check{S}_A(f)$:

$$\check{S}_A(f) = \check{S}_Y(f)L \text{sinc}(fL/v) \quad (25)$$

Using equation 25, by inverse Fourier transform, we finally get:

$$A(t) = F^{-1} \left[\check{S}_A(f) \right] \quad (26)$$

Equations 25 and 26 model the time evolution of rain attenuation described by the SST.

Let us recall some useful theorems (Matricciani 1996) and calculate equation 25 at $f = 0$. From Fourier transform theory, we get

$$\check{S}_A(0) = L \check{S}_Y(0) = L \int_0^{T_R} kR^\alpha(t) dt \quad (27)$$

where T_R is the duration of the rain rate event measured at the rain gauge. Equation 27 states that $\check{S}_A(0)$ is independent of v , and that for a rain event it is a constant. This property is just a consequence of the conservation of the quantity of water Q (mm) collected by the rain gauge during the rain event:

$$Q = \int_0^{T_R} R(t) dt \quad (28)$$

Now $\check{S}_A(0)$, by Fourier transform theory, is also given by

$$\check{S}_A(0) = \int_0^{T_A} A(t) dt = \text{constant} \quad (29)$$

In equation 29, T_A is the duration of the rain attenuation event as measured by the radio link. Notice that this conservation law (equation 29) holds in the time domain but not in the space domain, because in this latter case the

linear extension of the rainy area, $R(x)$, along the direction of the horizontal path (and storm motion, because of the assumed statistical isotropy), depends on v and is given by

$$D_R = v T_R \quad (30)$$

Therefore, T_A must be given by

$$T_A = \frac{D_R + L_R}{v} = T_R + \frac{L}{v} \quad (31)$$

where L/v is the time during which the path is partially under rain but the rain gauge is not.

Notice that, when $v \rightarrow \infty$, the duration of the attenuation event coincides with the duration of the rain event; hence, in general the probability that it rains at a site as measured by a rain gauge is smaller than that measured by the radio link, and the two become approximately equal only for high storm speeds.

If, for a given rain rate pattern, v increases, then according to equation 31 the duration of the attenuation event decreases, and vice versa. In both cases, and regardless of v , according to equation 29 the area under $A(t)$ is always a constant; as a consequence, if the duration of the attenuation event is shorter than that relative to a reference speed, on average its attenuation must increase to hold the area constant, and vice versa. Hence, the same rain rate pattern can give attenuation events of different durations and peak attenuations, both functions of v of the rainstorm, although the long-term probability distributions of rain attenuation are not very sensitive to the average value of v (Matricciani 1996; Matricciani and Moretti 1998).

It is interesting and useful, though not physical, to find $A(t)$ when v approaches infinity. From equations 25 and 26 we get

$$\lim_{v \rightarrow \infty} A(t) = kR^\alpha(t)L \quad (32)$$

This expression yields a uniform rain rate pattern along the path. When $v \rightarrow \infty$, the transfer function in equation 25 becomes the constant L —that is, an all-pass ideal transfer function and $D_R \rightarrow \infty$. Equation 32, of course, satisfies the conservation law in equations 28 and 29.

Let us now apply the theory to a *satellite* radio link (i.e., to a slant path). Let θ be the path elevation angle and ξ the slant coordinate (see Figure 2). Then, according to the two-layer vertical structure of precipitation, equation 1 becomes

$$A(x_0) = k_A \int_0^{L_A} R^{\alpha_A}(x_0 + \Delta x_0, \xi) d\xi + k_B r^{\alpha_B} \int_{L_A}^{L_B} R^{\alpha_B}(x_0, \xi) d\xi \quad (33)$$

Table 3 reports the values of k and α for selected frequencies, available from ITU-R (1992a) or Maggiori (1981).

Notice that, in the first term of the right-hand side of equation 33, we must introduce a shift Δx_0 , because the path enters layer A at $x_0 + \Delta x_0$ (see Figure 2).

Figure 2: A slant path to a satellite
 Note: The storm moves from right to left with constant speed v . The slant path first encounters layer B at abscissa x_0 and height $H_A + h$, then layer A at abscissa $x_0 + \Delta x_0$ and height H_A

Table 3: Values of k and α for Circular Polarization and Selected Carrier Frequencies

f (GHz)	Layer B (0°C)		Layer A (20°C)	
	k	α	k	α
12	0.0186	1.161	0.0178	1.221
20	0.0643	1.102	0.0722	1.083
30	0.1701	1.027	0.1780	1.007

The rainy paths in equation 33 are given by:

$$L = \frac{H - H_S}{\sin \theta} \quad (34)$$

Equation 34 yields L_B when $H = H_B$ and L_A when $H = H_A$. H_S is the altitude of the station above sea level, and

$$\Delta x_0 = \Delta L \cos \theta = h / \tan \theta \quad (35)$$

$$\Delta L = L_B - L_A = h / \sin \theta \quad (36)$$

Fourier transform of equation 33 gives:

$$S_A(f_s) = S_{Y,A}(f_s) L_A \text{sinc}(f_s L_A) \exp(-j2\pi f_s \Delta x_0) + r^{\alpha_B} S_{Y,B}(f_s) \Delta L \text{sinc}(f_s \Delta L) \quad (37)$$

$$S_{Y,A}(f_s) = F[k_A R^{\alpha_A}(x)] \quad (38a)$$

$$S_{Y,B}(f_s) = F[k_B R^{\alpha_B}(x)] \quad (38b)$$

Now, since the speed along the slant path is given by $v(\theta) = v/\cos\theta$, the space spectrum is transformed into the conventional temporal spectrum with $f = v f_s / \cos\theta$ (Hz) as:

$$\check{S}_A(f) = \check{S}_{Y,A}(f) L_A \text{sinc}(f L_A / v(\theta)) \exp(-j2\pi f \Delta x_0 / v(\theta)) + r^{\alpha_B} \check{S}_{Y,B}(f) \Delta L \text{sinc}(f \Delta L / v(\theta)) \quad (39)$$

$$\check{S}_{Y,A}(f) = F\{Y_A(t)\} \quad (40a)$$

$$\check{S}_{Y,B}(f) = F Y_B(t) \quad (40b)$$

Finally, $A(t)$ is given by equation 26. Equation 39 satisfies, of course, the conservation law (equations 28 and 29); equation 31 holds also for slant paths (in this case, L represents the path length projected at ground).

Notice that, if $\theta = 90^\circ$ (vertical path), then $v(\theta) \rightarrow \infty$, and, from equations 39, 36, and 26, $A(t)$ is given by

$$A(t) = k_A R^{\alpha_A}(t)(H_A - H_S) + r^{\alpha_B} k_B R^{\alpha_B}(t)h \quad (41)$$

For $\theta \neq 90^\circ$ and $v \rightarrow \infty$ from equations 39 and 36 we get again the all-pass model (equation 32):

$$\lim_{v \rightarrow \infty} A(t) = k_A R^{\alpha_A}(t) L_A + r^{\alpha_B} k_B R^{\alpha_B}(t)(L_B - L_A) \quad (42)$$

Notice that, from equation 42 or 41, we can calculate a rain attenuation probability distribution without any simulation, by just inserting the values of rain rate exceeded with a given probability: the computed attenuation is predicted to be exceeded with the same probability. In this case, it suffices to know the cPdf of rain rate R to obtain the cPdf of A , as the latter, calculated from equation 41 or 42, is exceeded with the same probability. An estimate of the cPdf of rain rate R is provided by global maps of rain rate exceeded for several annual probabilities by the ITU-R (2001a).

Equation 42 can be used to calculate, with good confidence, rain attenuation for low values of rain rate (up to about 10 mm/h). At higher values, equation 42 gives pessimistic values. A better estimate of the SST predictions without the necessity of running the SST can be estimated by the relationship

$$A_v = a A_\infty^b \quad (43)$$

which links the value A_∞ (dB), estimated by equation 42, with the value A_v (dB); calculated with the SST, both

Figure 3: Scattergram of rain attenuation A_{SST} (dB) calculated with the SST (equations 39 and 26), with $v = 10.6$ m/s, as a function of rain attenuation, A_{∞} (dB), calculated by assuming $v = \infty$ m/s (equation 42), for frequencies in the range of 10–30 GHz, in a 37.8 degree slant path to Italsat at Spino d'Adda (Northern Italy). The continuous line gives the best fit (equation 43); the dashed line is 45 degrees.

exceeded with the same probability. Let A_{SST} be the exact value estimated by equations 39 and 26. If we define the percentage error committed in using equation 43 as

$$\varepsilon = 100 \times \frac{A_{SST} - A_v}{A_v} \quad (44)$$

then the power law (equation 43) is reliable and tight enough (Figure 3), with small errors in large frequency ranges, as it is shown in Table 4, which also reports the values of the constants a and b . In other words, we can apply equation 43 to get the long-term cPdf of rain attenuation without the need to know the rain rate time series, which may not be available. Although equation 43 refers to a particular set of radio electrical and geographical parameters (Figure 3), its validity should be more global because it links rain attenuation calculated with rain rate data of a site to that obtainable with the SST at the same site.

Rain Attenuation Statistics for Mobile-System Satellite Communications

Rain attenuation statistics applicable to mobile satellite communication systems can be very different from those applicable to fixed terminals, linked to the same satellite, because of the relative motion of rainstorms and vehicles (Matricciani 1995, 2000a; Matricciani and Moretti 1998; Matricciani and Selva 2002). Mobile satellite communication is not affected, of course, only by rain but also by shadowing and multipath. These disturbances can plague the channel for such a long time that they establish system performance for a large range of outage probabilities, including the very low ones when rain attenuation contributes to the outage. Notice, however, that at the end of a future technological breakthrough in *smart* antennas (phased arrays with much signal processing), which may largely reduce the impact of multipath by ad hoc processing, rain will remain the irreducible cause of fading and system outage, if obstruction and shadowing are not present.

Models of Vehicle Speed

To obtain realistic values of the rain attenuation measured by a mobile terminal, we must know a reliable estimate of the probability distribution of the speed of vehicles, v_M , in different traffic and route conditions. Curiously, most literature reports more data on vehicular traffic (e.g., the number of vehicles running through a check point in a given interval of time) than vehicular speed.

The long-term Pdf of vehicular speed can be modeled by a log-normal distribution, at least for European traffic and for the three types of traffic and roads considered by Matricciani and Moretti (1998):

1. Urban routes with low-speed traffic (Model I)
2. Urban and suburban routes with high-speed traffic (Model II)
3. Freeway routes with very high-speed traffic (Model III)

For all three models, the standard deviation of $\ln v_M$ is the same— $\sigma = 0.221$ —and the median values (obtained from the averages of $\ln v_M$) are 30.1 km/h (Model I), 56.0 km/h (Model II), and 117.1 km/h (Model III).

Scaling Rain Attenuation Statistics from Fixed Systems

When a site and the cPdf of exceeding a given rain attenuation A (dB) in a fixed satellite system, $P_f(A)$, are considered (see the section entitled “Rain Attenuation Statistics for Fixed-System Satellite Communications”), it is implicitly assumed that $P_f(A)$ is applicable to sites belonging to

Table 4: Values of a and b to Be Inserted in Equation 43 for Two Wide-Frequency Ranges and Percentage Errors

Frequency Range (GHz)	a	b	Average Error $\langle \varepsilon \rangle$ (%)	Standard Deviation σ (%)
10–30	0.958	0.960	0.08	9.6
10–100	0.973	0.938	0.13	7.8

a more-or-less large homogeneous geographical area centered at this site (neglecting possible orographic effects). Now, vehicles driven within this same area (and started inside or outside the area) are affected by the same rain attenuation of the fixed terminals located at the same point, but for different intervals of time, so that they measure a cPdf, $P_M(A)$, that may not coincide with $P_F(A)$, as well as different statistics of fade duration and rate of change of fade compared to a fixed terminal (Matricciani 1995).

A designer needs to know how the first-order statistic $P_F(A)$ is transformed into that applicable to a GEO or MEO satellite system for any mobile terminal, $P_M(A)$, working in the same geographical area, at the same carrier frequency, and in the same weather conditions. Matricciani (1995) has shown that $P_M(A)$ can be scaled from $P_F(A)$ according to the simple expression

$$P_M(A) = \xi(A)P_F(A) \quad (45)$$

Note that, to a first approximation, the dependence on the attenuation in the scaling factor ξ can be safely ignored because of equation 3. In other words, for a given vehicle pattern, we can scale $P_F(A)$ (e.g., estimated with the SST) to $P_M(A)$ by applying a constant value ξ (see following text).

Now, in a definite geographical area, at any given time a fraction q_{in} of the total number of vehicles moving in it may be started from inside the area (and eventually leave it, as is here assumed, by entering a contiguous area), and a fraction $q_{out} = 1 - q_{in}$ may be driven into the area from its perimeter. Realistic values of q_{in} must be estimated from traffic measurements or models. These two mutually exclusive cases can yield two quite different distributions, $P_{M,in}(A)$ and $P_{M,out}(A)$, respectively, which can be estimated separately and, once known, are necessary to design satellite communication systems for *any* vehicle driven within the area.

If $P_{M,in}(A)$ and $P_{M,out}(A)$ are known for a given pattern, then the land-mobile satellite system for that pattern can be designed, regardless of the origin of the user, just by weighting the two distributions according to the value of q_{in} to obtain the overall cPdf, $P_M(A)$, as

$$P_M(A) = q_{in}P_{M,in}(A) + (1 - q_{in})P_{M,out}(A) \quad (46)$$

Equation 46 can be generalized to determine the cPdf of rain attenuation in a larger area made up of smaller areas with homogeneous rain rate statistics, or an area made up of cPdfs relative to different values of a parameter (e.g., pattern, elevation angle, speed model, etc.) by adding many terms weighted accordingly.

In conclusion, from equation 45 and by assuming constant values of ξ_{in} and ξ_{out} , equation 46 can be written as

$$P_M(A) = [q_{in}\xi_{in} + (1 - q_{in})\xi_{out}] P_F(A) \quad (47)$$

Equation 47 is very useful because it directly yields $P_M(A)$ as a function of $P_F(A)$ for any vehicle started inside or outside the area.

The results summarized as follows refer to a GEO satellite receiver at 19.77 GHz with elevation angle $\theta = 30.6^\circ$ (Matricciani 2000a), and to a MEO satellite receiver with minimum elevation angle $\theta \geq \theta_{min} = 30.6^\circ$ (Matricciani and Selva 2002) located in the Po Valley (Northern Italy). The GEO satellite receiver is affected, on the average, by a larger attenuation than the MEO satellite receiver as a result of a smaller elevation angle. Although the results refer to specific systems and locations, the findings are of general applicability.

To obtain the empirical rules to transform $P_F(A)$ into $P_M(A)$ for the same rain attenuation $A_F = A_M = A$ (dB), we can consider three likely patterns, according to how vehicles are driven: (a) *zigzag routes*; (b) *ring-roads*, to simulate city patterns; and (c) *straight routes* to simulate freeways. The simulations consider a very large number of rain rate circular maps of 80 km in diameter, measured by a meteorological radar located in Spino d'Adda (45.5 degrees north, 9.5 degrees east, 84 m above sea level), in a flat countryside near Milan (Italy), collected during rainstorms randomly observed in 1989, 1991, and 1992 (Matricciani 2000a; Matricciani and Selva 2002). The rain rate maps were sampled every ninety seconds. On these maps a grid of square cells was superposed to represent city blocks and streets in cases (a) and (b), and straight lines in case (c). Now, since meteorological radars provide a reliable estimate of the horizontal structure of rain, the results can stand as experimental for both fixed and mobile satellite systems.

Similar results could also be derived by applying a bidimensional version of SST (Matricciani and Moretti 1998) instead of using radar maps. The SST simulations are very useful because they can be applied to any site and its surroundings for which only rain rate time series are available.

The results have shown that in zigzag routes, for both GEO and MEO satellite systems, it is always $P_M(A) < P_F(A)$. The detailed results depend on vehicle speed modeling and starting conditions (i.e., inside or outside the observed area). In ring roads, there is no improvement compared to the fixed system, $P_M(A) \approx P_F(A)$. In straight freeways, vehicles are always started outside and cross the entire area (i.e., $q_{in} = 0$). In this case, the results show that $P_M(A) \ll P_F(A) \cdot P_M(A)$, however, can change significantly in different routes and in opposite directions (anisotropy and asymmetry) for medium-large attenuation. Only at low attenuation are different directions and routes indistinguishable (isotropy and symmetry). When compared to zigzag routes or ring roads, the performance of vehicles driven in freeways is the most optimistic.

Figure 4 shows the cumulative time that rain attenuation A (dB) in abscissa is exceeded in the GEO and MEO satellite systems for fixed terminals and for vehicles running in straight freeways with speed values according to Model III (fast traffic) or Model I (low traffic, simulating a slower traffic in freeways). The results are averaged over all directions. As expected, for the same cumulative time exceeded (or probability: the corresponding cPdfs can be obtained by dividing the cumulative time by the same observation time without changing the comparison), the GEO satellite system is affected by a larger attenuation than the MEO satellite system with the same minimum elevation angle, $\theta \geq \theta_{min} = 30.6^\circ$.

Figure 4: Cumulative time (minutes) that rain attenuation A (dB), at 19.77 GHz, in abscissa is exceeded in the GEO fixed system (curve label “fixed GEO”) and MEO satellite systems for fixed terminals (curve labeled “fixed”), as well as for vehicles running in straight freeways with vehicle speed values according to Model III (fast traffic) or Model I (simulating slow traffic). The latter distributions must be compared to the curve labeled “fixed.”

From Figure 4 we can obtain the probability scaling factor $\xi(A)$ for the MEO system shown in Figure 5. This figure also shows the scaling factors obtained for a GEO satellite system (Matricciani 2000b). Notice that for both MEO and GEO systems, $\xi(A)$ is not significantly different for the same patterns; for most of the attenuation range, it is practically independent of attenuation (and carrier frequency), so that a single value can be used (similar to the zigzag routes). For low attenuation, $\xi(A)$ approaches a higher value because in this range vehicles encounter low rain rates that are likely to cover large parts of the circular area, as opposed to more intense rain rates. Figure 4 shows that $\xi(A) < 0.1$ for the fast traffic (for freeways, fast traffic $\xi = \xi_{out}$ because $q_{in} = 0$), and $\xi(A) < 0.4$ for the slower traffic.

As for zigzag routes in urban or suburban traffic, Table 5 reports the constant values of ξ_{out} and ξ_{in} for speed Models I and II, respectively. For GEO and MEO mobile systems,

Figure 5: Probability factor $\xi(A)$ as a function of rain attenuation A (dB) at 19.77 GHz for comparable GEO (dashed lines) and MEO (continuous lines) satellite systems in the same geographical area for vehicle speed Model I (slow traffic) and Model II (fast traffic).

the values of ξ are still not significantly different for the same patterns.

Second-order statistics of the fixed system are scaled to the mobile system accordingly. A fade duration must be multiplied by $\xi(A)$, and a rate of change must be divided by $\xi(A)$, for a given rain attenuation A (Matricciani 1995). For the most optimistic case (i.e., vehicles or trains) running fast in straight freeways (speed Model III), fade duration measured by a fixed receiver may be largely “shrunk” because $\xi(A) \leq 0.1$. This is a benign effect because it reduces, for a given system power margin, the duration of outages. On the other hand, the rate of change measured by a fixed receiver is now emphasized because it is multiplied by $1/\xi(A) \geq 10$, and this fact can have a significant impact on the methods that dynamically adjust some system parameters according to the instantaneous rate of change of attenuation (e.g., power margin, adaptive coding, satellite tracking, etc.), in the past designed to cope with the fixed system rates of change. Table 6 summarizes the main findings.

Table 5: Average Value of the Probability Factor ξ_{out} and ξ_{in} Zigzag Routes as a Function of p_s , ξ_{out} , and ξ_{in} (in the Range of $1 \leq A \leq 30$ dB at 19.77 GHz)

Probability of Going Straight p_s	ξ_{out} (Vehicles Started from the Perimeter of the Useful Area)				ξ_{in} (Vehicles Started Inside the Useful Area)

Table 6: First- and Second-Order Statistics of Rain Attenuation for Land-Mobile Satellite Communication as a Function of Those Measured (or Estimated) in Fixed-System Satellite Communication

Rain Attenuation Statistic for Land-Mobile Communication	Ring Roads	Zigzag Routes (see Table 4)	Freeways (see Figure 5)
Probability distribution $P_M(A)$	$P_M(A) \approx P_F(A)$	$P_M(A) = [q_{in}\xi_{in} + (1 - q_{in})\xi_{out}]P_F(A)$	$P_M(A) = \xi P_F(A)$
Fade duration $D_M(A)$ (min)	$D_M(A) \approx D_F(A)$	$D_M(A) = [q_{in}\xi_{in} + (1 - q_{in})\xi_{out}]D_F(A)$	$D_M(A) = \xi D_F(A)$
Rate of change of fade $R_M(A)$ (dB/s)	$R_M(A) \approx R_F(A)$	$R_M(A) = \frac{R_F(A)}{[q_{in}\xi_{in} + (1 - q_{in})\xi_{out}]}$	$R_M(A) = \frac{R_F(A)}{\xi}$

CONCLUSION

Land-mobile satellite communication can be degraded much more seriously than fixed-satellite channels because electromagnetic waves propagate in a high hostile environment made of obstructions, shadowing, multipath, hydrometeors, and other constituents of the atmosphere. The frequency bands now used are L band (1.5 GHz) and S band (3 GHz), but the large bandwidths allocated at K_u (12/14 GHz) band and K_a band (20/30 GHz), and the availability of a mature technology for these frequency bands, have made them more attractive for satellite broadband multimedia services. However, besides suffering the same propagation impairments of L and S bands, these bands are also affected by large fading due to the troposphere—mainly rain attenuation. We have recalled the most important radio electrical aspects (modulation, coding, multiple access, and orbits) applicable to a land-mobile satellite channel, and we have summarized in more detail the modeling of the physical channel in clear-sky and rainy conditions.

For clear-sky conditions there are so many models, especially for the more common and simple case of narrow-band channels, that it is very difficult to design a system without knowing the type of environment the mobile terminal will find on route. Most of the models are empirical, and, as such, they do not allow insight into the physical causes that cause fading; therefore, deeper understanding and extrapolation to other sites and environments are not straight. Other models are theoretical and characterized by well-known probability distributions, often used jointly to describe more complex situations but always conditioned to a given “known” environment, which is hard to set in real time.

Although channel modeling concerning rain attenuation is, in principle, easier because the cause of fading can be well identified (rainfall), it may be difficult to know, for an area, the representative rain rate time series and to apply the synthetic storm technique—a physical, reliable, and powerful prediction tool—to obtain first- and second-order statistics of rain attenuation applicable to fixed systems first and to land-mobile systems second by scaling them according to the appropriate scaling factor, ξ .

The need to know the rain rate time series for a given locality is overcome when only a first-order statistic (i.e., the long-term probability distribution of rain attenuation) is required because this can be obtained by equations 42 and 43, and ITU-R global maps of rain rate as a function

of probability. These predictions are approximately as reliable and accurate as those provided directly by the synthetic storm technique.

In conclusion, for both clear-sky and rainy conditions, ad hoc modeling and propagation expertise are as much of a necessity for land-mobile satellite communications as for their terrestrial counterparts, especially at frequencies greater than 10 GHz.

GLOSSARY

BPSK: Binary phase shift keying.

C band: Channels at approximately 4/6 GHz (downlink/uplink).

CDMA: Direct-sequence code division multiple access.

FDMA: Frequency division multiple access.

FEC codes: Forward error correcting codes.

GEO: Geostationary Earth orbit.

K_a band: Channels at approximately at 20/30 GHz (downlink/uplink).

K_u band: Channels at approximately 12/14 GHz (downlink/uplink).

L band: Channels at approximately 1.5 GHz.

LDPC codes: Low-density parity check codes.

LEO: Low-altitude Earth orbit.

MEO: Medium-altitude Earth orbit.

QPSK: Quadrature phase shift keying.

S band: Channels at approximately 3 GHz.

SST: Synthetic storm technique.

TDMA: Time-division multiple access.
